coupled online with the widely used and efficient *C*₁₈ analytical column, but could be used with a PGC analytical column. Separations on *C*₁₈ is achieved with water-rich mobile phases, which are unable to desorb analytes that are more retained by PGC pre-column. Band broadening, the influence of the matrix, and recoveries were evaluated. For example, retention of 4-aminophenol on PGC, which is not retained on *C*₁₈ and only slightly on PRP-1, was 10 times higher in compared with PRP-1.

The other carbon materials recommended for phenol extraction are GCBs. They are nonporous sorbents with surface areas ranging from 8 to 100 m² g⁻¹. The adsorbent contains chemical heterogeneities on its surface. In the presence of water, these surface to form positively charged impurities. Thus GCB behaves both as a nonspecific sorbent and an anion exchanger. This feature is used for rapid and simple isolation of acidic analytes from co-extracted base-neutral species by differential elution. Elution by neutral eluents allows for transfer to solution of base-neutral and very weak acidic compounds. The most acidic compounds (e.g. phenols having *pK*_a values lower than 7) remain on the adsorbent and may be transferred to the solution by the acidified eluent. Commercially referred to as Carbograph 1 or Car-

bopack, GCB has proved to be a valuable sorbant for SPE. However, it was demonstrated that Carbograph 4 is more efficient than Carbograph 1 in extracting very polar compounds from large volumes of water (Table 3). A robust and selective liquid chromatography method was developed enabling rapid determination of 11 US EPA phenols in samples in the ng L⁻¹ range. The method involved extraction of phenols by a reversible 0.5 g Carbograph 4 cartridge and re-extraction by an eluent containing a quaternary ammonium salt. Phenols were directly analysed by LC-UV, after derivatization to appropriate acetyl derivatives. Recovery of phenols was higher than 90%.

SPE of Phenols on Anion Exchangers

For phenol analysis, synthetic anion exchangers (polymers and chemical-bonded silicas) are generally applied because of their durability and chemical resistance. The typical functional groups of strong or weak basic anion exchangers are $-\text{CH}_2-\text{N}^+(\text{CH}_3)_3$ and $-\text{N}^+\text{H}(\text{R})_2^-$ respectively.

An application of ion exchangers for selective determination of phenols in water by a two-trap tandem extraction system followed by LC has been proposed. The first extraction column was filled with 300 mg GCB and the second with 50 mg of a strong anion exchanger (SAX, commercially referred to as Sephadex QAE A-25). After the water sample had

been passed through the GCB cartridge, the latter was connected to the SAX cartridge. Base-neutral species adsorbed on GCB were removed by a neutral eluent. Co-eluted, very weakly acidic phenols were selectively re-adsorbed on the SAX sorbants. Next, avoiding disconnection of the cartridges, an acidified eluent was allowed to flow through the two cartridges to recover the most acidic phenols from the GCB and the least acidic phenols from the SAX. After partial removal of the solvent, the final extract was analysed by LC-UV. Recoveries of 17 phenols added to 2 L of drinking water were higher than 90%.

Recoveries from 1 L of tap water and seawaters are presented in Table 4. In one process it was possible to concentrate both more and less polar phenols. The method is characterized by high selectivity; only acidic organic compounds can interfere with the phenols. Anionic surfactants (frequently occurring in aqueous environmental samples) are not eluted, because the formic acid contained in the second mobile phase is unable to displace the anionic surfactants from positively charged sorption sites populating the GCB surface.

Solid-phase Microextraction of Phenols

SPME can be used to concentrate volatile, semivolatile and nonvolatile phenols in both liquid

and gaseous samples. This method, in which sorbent-coated silica fibres are used to extract analytes, is superior to other sample preparation methods. The fibre is introduced into the sample or headspace and phenols (or other organic substances) establish equilibrium and partition on to the phase. Next, the analytes are thermally desorbed from the fibre to the gas chromatograph. SPME is a fast, simple and sensitive technique which does not require the use of solvents. The method is significantly simpler than conventional SPE, thereby reducing the potential for loss of analyte during the extraction process. Most of the SPME methods are based on a poly(dimethylsiloxane) coating, which is relatively nonpolar. In the case of phenol extraction, it is necessary to use a more polar phase or a derivatization procedure to reduce their polarity and improve chromatographic properties.

The basis of SPME optimization for the determination of phenols was established by Buchholz and Pawliszyn. The subject of the research was to evaluate the derivatization step by increasing the affinity of the phenols for the poly(dimethylsiloxane) coating, comparison of the affinity of phenols for the poly(dimethylsiloxane) coating and a more selective, polar coating (a poly(acrylate)), the influence of acid and salt on the enhancement of phenols, evaluation of time equilibration on the equilibrium distribution constant between a solid-phase coating and water and an evaluation of the above parameters on carry-over. Headspace analysis of phenols was also evaluated. The most important conclusions are:

- The poly(dimethylsiloxane) coating is not suitable for extracting phenol; some chlorophenols and nitrophenols could not be extracted in large enough amounts to be detected by GC.
- The derivatization procedure created compounds with higher affinity for the poly(dimethylsiloxane) coating; the amount of acetate extracted for most of the target analytes was several times greater than the free form (2-nitrophenol was the only compound for which the amount of derivative extracted was less than the free phenol). It was demonstrated that the *in situ* derivatization can be performed directly in the polymeric coating.
- Phenol acetates have significantly better peak shape than the free phenols.
- Poly(acrylate) coating was successful in extracting both polar and nonpolar compounds; the fibre only slightly favours the polar phenols over its nonpolar analogues.
- Only 15 min is required for all analytes to equilibrate with the poly(dimethylsiloxane) coating; with poly(acrylate)-coated fibres, 40 min was required. That can be explained by the fact that the poly(dimethylsiloxane) phase is a liquid, whereas the poly(acrylate) phase is a solid.
- When the extraction is performed under saturated salt condition, 5.5 times more phenol was extracted compared to the control sample (sample of the same concentration at neutral pH and with no salt added).
- The salting-out effect was observed for high pK_a phenols; this results in a positive increase in the

amount extracted for these phenols; for phenols which have a considerable portion of their molecules in the ionized form, the salting-out effect is a negative factor.

- Matrix significantly affects the extraction of phenols, especially nitrophenols and heavier chlorinated phenols. These effects can be overcome by normalization to extreme acid and salt conditions. Headspace is another method of reducing matrix influence.
- If the fibre is directly exposed to samples which are high in particulate matter, material from the matrix could coat the solid phase and interfere with extraction. To avoid this, the headspace above the liquid should be sampled. The success of this method depends on the transfer of analytes from the aqueous phase to the headspace. Most of the target phenols could be enriched in the headspace by decreasing their solubility in the aqueous phase through saturation with sodium chloride and acidification to pH below 1. However, even with these extreme conditions, most phenols needed 1–2 h to reach equilibrium.

Conclusions

The trace determination of phenols in environmental samples requires specific strategies. Analytical methods need to be sensitive selective, rapid and

simple. Both SPE and SPME techniques with a variety of sorbents for enrichment and purification are used. In the last decade, several online systems for SPE-LC or SPE-GC have been published. Online SPE procedures provide greater sensitivity, lower sample volumes, lower consumption of organic solvent, higher automation and better reproducibility. SPME is rarely applied and seems to vary with phenol concentration.

Thin-Layer (Planar) Chromatography

J. H. P. Tyman, Institute of Physical and Environmental Sciences, Brunel University, Middlesex, UK

Copyright © 2000 Academic Press

Introduction

Phenols have played an important part in thin-layer chromatography (TLC) since its inception as a general separatory method. The phenolic group occurs in a wide variety of natural replenishable organic compounds from the amino acids (tyrosine), the alkaloids (morphine), the steroids (estrone), glycosides (arbutin, carminic acid, flavonols), perfume ingredients (methyl salicylate, eugenol), phenolic lipids (cashew phenols, urushiol) and the tetracyclines to the cannabinoids. Fractions derived from fossil fuels by distillation or by synthesis contain phenol itself, the cresols, xlenols and polynuclear compounds. Many purely synthetic products, notably drugs (aspirin, paracetamol), technical products (*t*-butylphenol, nonylphenol, and other intermediates such as chloro- and nitrophenols extend the range of substances as candidates for TLC.

The classical separations of structural isomers of monohydric, dihydric and polyhydric phenols and their derivatives have generally formed the basis for subsequent applications to mixtures of more complex compounds. All these initial studies were essentially qualitative and have led over the past four decades to quantitative work aimed at the determination of a single phenolic substance in a mixture or of the total phenolic composition.

The original TLC adsorption method with silica gel was soon supplemented by the partition technique by coating the adsorbent with a paraffinic compound or by silanization. These reversed-phase (RP) approaches have, with the introduction of excellent commercial plates, led to the routine use of alkylsilylbonded silica gel with C₁₈, C₈ or C₂ silyl groups.

In a similar fashion, with the development of uniform particle size adsorbents high performance TLC

(HPTLC), combined techniques such as TLC-ultraviolet (TLC-UV), TLC-mass spectrometry (TLC-MS), (TLC-GLC) and TLC-high performance liquid chromatography (TLC-HPLC) have all been applied to the study of phenolic materials.

A wide variety of adsorbent layers have been investigated for the analysis of phenols, including silica gel, alumina, cellulose and polyamides as well as mixtures in certain cases with other inorganic materials such as calcium hydroxide or impregnated with organic additives. The use of argentation TLC with phenolic lipids is well established but other ions, for example Fe(III) and Cu(II), have found limited application.

Solvents from the whole elutropic range have been employed and frequently basic conditions have been found advantageous by the use of ammonia or by the addition of an organic base, although solvents acidified with formic acid have an application. With the availability of silica gel G₂₅₄, visualization of phenolic substrates is straightforward, although with non-indicating silica gel, the use of dichlorofluorescein, rhodamine 6G or a wide selection of spray reagents has become common practice and almost completely displaced the use of sulfuric acid and thermal charring. Documentation by means of photocopying, photography or by the use of dyeline paper and an ammoniated atmosphere are all effective methods.

In the following examples, the analytical scale TLC separations of a range of isomeric compounds are tabulated. At the preparative scale increased sample loading leads to a loss of resolution and indeed the loading/resolution factor should be examined in all cases.

Separation of Structural Isomers of Phenols and Phenolic Acids

The *R_F* values of an extensive range of phenolic compounds of synthetic and natural origin have been given in the literature listed in the Further Reading

section, notably in the Tables in Tyman (1996) and Hanai (1982).

Cresols

The separation of structural isomers represents an effective test of a chromatographic method and this is particularly relevant to TLC where a considerable body of work has been devoted to the *o*-, *m*- and *p*-derivatives of phenol. Thus, in Table 1 some results, from experiments covering a period of nearly four decades, are shown on the cresols. Marginal differences of R_F values are seen in solvent systems a–f, h, and less so in i. Remarkably, it is only recently that an acceptable separation has been achieved with system g involving silica gel G, although in this case a second run would be desirable if phenol itself were present in a commercial sample.

Ethylphenols

The *o*-, *m*- and *p*-isomer of the homologous ethylphenol might similarly be separated. Table 2 indicates four other systems which have been examined and only in system a with alumina is the separation well defined. A crucial factor of importance in isomer separations is the relative R_F values of the *m*- and *p*-isomers since a steric influence aids the differentiation of the *o*-isomer.

In the case of higher homologues, for example the isomeric *t*-butylphenols, silica gel (type 60) with benzene appears to be marginally more effective than alumina with diisopropyl ether or cellulose (by RP with aqueous ethanol), giving for the *o*-, *m*- and *p*-isomers R_F values of 54, 22 and 16 respectively.

Chlorophenols

The R_F values of the isomeric monochlorophenols are shown in Table 3. This series has been widely

Table 2 R_F Values of phenol and isomeric ethylphenols on various layers

studied by adsorption methods (b–e, g) and by partition procedures (a, f, h) and, generally, greater resolution has been found with the latter. Nevertheless, by the use of basic layers (b) or with basic solvents (c) almost comparable results are achieved. As with many isomeric compounds, the 3- and 4-isomers present the main problem.

Nitrophenols

The separation of the isomeric nitrophenols depicted in Table 4 presents relatively little difficulty and generally adsorption conditions (b–e) have proved as effective as others; the use of impregnated silanized silica gel (f) does not seem to aid the *o*-/*p*- compound separation. The increased polarity of the nitro group compared with the chloro substituent appears to help the separation of the 3- and 4-isomers.

Aminophenols

The isomeric aminophenols have been separated as shown in Table 5 on a diverse range of adsorbents and solvent systems, all of which have yielded acceptable separations, although system b, one of the most recently examined, is to be preferred above the others.

Dihydroxybenzenes

In a similar way, the dihydroxybenzenes have been studied widely and the same system as used for the aminophenols (Table 5, condition a) has afforded the best separation of the three isomers, as depicted in Table 6.

Hydroxybenzaldehydes and Hydroxyketones

In the carbonyl series, comparatively little work has been carried out on either the hydroxybenzaldehydes or ketones. Table 7 indicates that no single system

affects the separation of all three isomers and the use of system a with e would be desirable.

In the ketone series, 2- and 4-hydroxybenzophenones appear to be readily separable from benzophenone itself on silica gel GF in benzene, with hR_F values of 53, 0 and 63 respectively. In benzene-piperidine (9 : 1), the corresponding values were 59, 9 and 77.

Phenolic Acids

Experimentation on the separation of isomeric phenolic acids has been widespread and a number of systems have been introduced, as shown in Table 8. The prevalent use of mildly acidic or basic solvent systems is seen compared with previous separations. In system a the formic acid enhances the separation of the 2-isomer through increased H-bonding, while in b-d the use of a basic solvent generally improves the resolution of all the isomers. The acetic acid component of systems e and f is insufficient to influence the separation of the 3- and 4-isomers.

Some Qualitative Separations of Mixtures of Phenolic Derivatives

Natural Phenolic Acids

Many natural phenolic acids have a useful pharmacological activity and plant sources containing them have a phytotherapeutic function. The two-dimensional TLC separation of reference mixtures or of the plant extracts of *Polygonum amphibium* has been effected first by development with benzene-methanol-acetonitrile-acetic acid (80 : 10 : 5 : 5) and, after removal of the eluent by evaporation,

a second development at right angles is carried out with sodium formate–formic acid–water (10 : 1 : 200, w/v/v). The result of the first development is shown in Figure 1A and of a second development in Figure 1B. The formulae of the 14 acids are shown in Figure 2.

Methylation of 3-Pentadecylphenol

The methylol derivatives of 3-pentadecylphenol are of interest for the solvent extraction of the borate ion and are obtained by the methylation of 3-pentadecylphenol with formaldehyde, a reaction which affords mainly the 4- and 6-methylols, a minor proportion of the 2-isomer, the 2,4-, 2,6- and 2,4-dimethylols and some 2,4,6-trimethylol. The reaction mixture of isomeric compounds has been separated on silica gel G with light petroleum (60–80°C)–diethyl ether–dimethylformamide–acetic acid (75 : 85 : 5 : 1), as depicted in Figure 3. It is imperative to confirm the identity of bands by spectroscopic means and by the use of synthetic reference compounds in the 2-, 4- and 6-methylol series obtained in

the present instance by reduction of the corresponding phenolic acid or aldehyde.

Phenolic Components and Constituents of *Anacardium occidentale* (Cashew)

Mixtures of phenols and phenolic acids such as occur in the shell of the cashew are used as precursors for the manufacture of certain formaldehyde resins. They have been separated with diethyl ether–light petroleum (40–60°C)–formic acid (30 : 70 : 1), as shown in Figure 4 on silver-impregnated silica gel G, which also affords a separation of the saturated, 8Z-monoene, 8Z,11Z-diene and 8Z,11Z,14-triene constituents of each component phenol. In the absence of silver ion, the four main component phenols cardol, 2-methylcardol, cardanol and anacardic acid (each containing four constituents, $n = 0, 2, 4, 6$) have hR_F values 20, 36, 58 and 76 respectively. By contrast, in an ammoniated solvent with multiple development,

a system used subsequently for quantitative analysis and described later, the phenolic acid anacardic acid was retained at low hR_F and separated from the three other phenols.

Resorcinolic Compounds from Rye

The homologous cardol constituents in rye (*Cereale scale*) have been separated by the use of a two-way development involving a preliminary separation (direction 1) of the saturated, monoene and diene members on argentated silica gel with benzene-ethyl acetate (85:15) and then, after removal of the silver ion and impregnation of the silica gel with paraffin

oil, RP separation of the C_{13} to C_{29} homologues by development (direction 2) with acetone-methanol-water (60:15:25), as shown in Figure 5.

Factors Influencing the Separations of Phenolic Compounds

Although, as with many classes of organic compound, the nature of the adsorbent, of the functional groups and of the position of the solvent or solvent mixture in the relative elutropic series are dominant influences, phenols have a unique property in respect of the intramolecular hydrogen bonding of a considerable number of the *o*-functional groups with the hydroxyl group. The hR_F values of *o*-substituted phenols on silica gel under adsorption conditions extend over a wider numerical range than those of the corresponding *m*- and *p*-isomers. Strongly hydrogen-bonding groups such as NO_2 , CHO and Cl head the series, as do bulky alkyl groups which by contrast exert a purely steric effect.

This is seen particularly with 2,6-compounds with nonpolar substituents such as the 2,6-di-*t*-butyl derivatives which are important antioxidants. These very nonpolar compounds are also actually less polar than their methyl ethers. Table 9 depicts the hR_F values for a number of 2,6-disubstituted compounds. A steric factor operates in the 2,6-dialkylphenol series, where 2,6-dimethyl, 2,6-diethyl, 2,6-diisopropyl, 2,6-diallyl and 2,6-di-*sec*-butylphenol have hR_F values of 43, 63, 86, 54, 94 respectively compared with phenol, 9, and the 2,6-di-*t*-butylphenol, 94, on cellulose plates

Figure 2 Formulae of phenolic acids 1–14.

impregnated with *N*-methylformamide and developed in hexane (Table 9).

With the *m*- and *p*-series, the bR_F values of all compounds are nearly parallel. The NO_2 , CHO and Cl groups now simply exert a polar effect (and an electronic effect on the phenolic acidity) while alkyl groups have a minor steric role. The isomeric phenolic acids behave similarly with respect to hydrogen bonding. 2,3- 2,4- and 2,5-Disubstituted compounds compare with the monosubstituted 2-series while 3,4- and 3,5-disubstituted compounds compare with 4-monosubstituted phenols.

Although current theory has no predictive use for structural assignment of polysubstituted compounds from their bR_F values, nevertheless the vast number of such values available from the literature affords a guide to the selection of an appropriate system. There is little doubt that solvent selection is the most important influence, as illustrated in **Table 1** where, with virtually the same adsorbent in entries (c) and (g), a period of 40 years separates a relatively poor from an excellent resolution, obtained simply by the addition of isopropanol to the same solvent.

Figure 3 Separation of methylol derivatives of 3-pentadecylphenol. A, 2-methylol; B, 6-methylol; C, 4-methylol; D, mixture of 2-methylol, 2,6-dimethylol and 2,4-dimethylol; E, 4,6-dimethylol; F, 4,6-dimethylol; G, 2,4,6-trimethylol; H, mixture of all the synthetic methylols. (Adapted with permission from Tyman, 1996a.)

This crucial role of the solvent is seen in the R_F values of certain hydroxyanthraquinones, depicted in **Figure 6**, where the advantage of hydrogen bonding in affording a separation of compounds 1 and 2 from 3 and 4 is sacrificed with the use of the polar solvents *n*-butanol or ethyl acetate. It is perhaps relevant to reiterate the value of the Stahl triangle (**Figure 7**) for separations to be effected under adsorption conditions.

Quantitative Separation of Mixtures of Phenolic Compounds

A variety of applications of TLC to the analysis of phenolic compounds in biochemical, environmental, industrial and consumer products has been summarized by Tyman (1996). In the following descriptions a selected range of quantitative studies are given. In the first the phenolic components of natural

cashew nut-shell liquid (CNSL), comprising anacardic acid, cardol, 2-methylcardol and cardanol, have been determined by the preferred method of densitometry, 'on the plate' and also by UV spectrophotometry 'off the plate'. The natural product is essentially a mixture of a phenol, a resorcinol, a hindered resorcinol and a phenolic acid. Its composition is required to assess the effectiveness of its industrial thermal decarboxylation at 200°C for obtaining technical CNSL, a product widely used in friction dusts for use in automobile brake and clutch systems.

Composition of Natural Cashew Nut-shell Liquid from *Anacardium occidentale* by Densitometry

Following lengthy experimentation, multiple development was used, initially with light petroleum (40–60°C)–diethyl ether–ammonia solution (50:50:5) to separate cardanol, 2-methylcardol from cardol/ammonium anacardate and then with diethyl ether–ammonia (90:10) to separate cardol and ammonium anacardate. The hR_F values were ammonium anacardate (0), cardol (36), 2-methylcardol (61) and cardanol (71). Subsequently, for the analysis of technical CNSL, which contains predominantly cardanol, cardol and 2-methylcardol, the alternative solvent system light petroleum–diethyl ether–formic acid (70:30:1) was employed, in which the hR_F values are 58, 20 and 36 respectively.

The natural product was obtained from frozen raw cashew nuts by cracking followed by solvent extraction and recovery at ambient temperature. Commercial silica gel G plates (20 × 20 cm) were used and multiple development in an ammoniated solvent system with 10, 20 and 30 µL of the unknown sample applied alongside 10, 16, 20, 24 and 30 µL of a standard solution containing anacardic acid, cardol, 2-methylcardol and cardanol. After development, removal of the solvent, visualization with iodine, the use of a cover plate and both horizontal and vertical scanning, the areas of all the bands were obtained by integration. A typical plate is illustrated in **Figure 8**.

Figure 4 TLC of cashew phenols before and after hydrogenation on silica gel G with 10% silver nitrate. Samples 1, 3, 5 and 7 are cardol, 2-methylcardol, cardanol and anacardic acid. Samples 2, 4, 6 and 8 are the hydrogenated samples showing absence of unsaturated constituents. Detection with sulfuric acid and charring. (Adapted with permission from Tyman, 1996a.)

Plots of area by densitometry versus volume (μL) of the standard solution for each standard phenolic component gave a series of straight lines conforming to the relation $y = mx$, to which the least-squares method was applied in order to determine accurately the slope m .

From the resultant plots and the areas by densitometry, the volumes (equivalent μL) of the unknown solution were ascertained. By simple proportionation relative to the known weights of the four phenols in the volume of standard solution used, the weights of the four component phenols in the unknown were then found. Table 10 depicts some results of two runs from a total of nine experiments. The average recovery (natural CNSL found/weight taken) was 98.0%.

Elution and Indirect Spectrophotometry

In the 'off the plate' method the same ammoniated system was used with multiple development, the

Figure 5 Two dimensional separation of 5-alkenylresorcinol homologues. Development 1 was first to 5 cm and then to 8 cm. Development 2 was at right angles. Detection was with Fast Blue B. A, saturated; B, monoene, C, diene constituents; S, starting point. Numbers 1–7 represent C_{13} to C_{25} respectively. (Adapted with permission from Tyman, 1996a.)

bands were visualized with Rhodamine 6G, removed from the plate and then eluted to recover the phenolic components which, after freeing from indicator by acidification, were made up to standard volume and examined by UV spectrophotometry. From the epsilon values $[(E\ 1\% \ 1\text{ cm} \times \text{mol. wt})/10]$ found, after correction for the purity of the phenols from the values of pure standards, the weights of the four component phenols were obtained and hence the percentage composition. The UV absorption of the four phenols is depicted in Figure 9.

It is of interest to compare the compositional analyses of natural CNSL by densitometry, gas chromatography (GC) and high performance liquid chromatography (HPCL) as depicted in Table 11.

TLC methods have also been employed with the phenolic lipid urushiol from *Rhus vernicifera*.

Determination of Phenolic Compounds, Mangiferin, Colladin and Colladonin in *Colladonia triquetra*

The natural product mangiferin (15), 2- β -D-glucopyranosyl-1,3,6,7-tetrahydroxy-9H-xanthene-9-one, which possesses mono hydrogen-bonded resorcinol

Figure 7 The Stahl triangle. Open circles, (1) emodin; closed circles, (2) xanthopurpurin; triangles, (3) Physcion; crosses, (4) chrysazin. (Reproduced with permission from Tyman and Morris, 1967.)

and catechol moieties in its structure, occurs as the major component in the Bulgarian medicinal plant *Colladonia triquetra* and is useful for cardiotonic, spasmolytic, diuretic and in other phytotherapeutic applications. In connection with agricultural production an improved analysis was developed for mangiferin by TLC and compared with an HPLC method. Colladin and colladonin are minor components in the natural product extracted.

Seeds of the natural product (2 g) were extracted with hot methanol and after recovery by concentration the residual material was dissolved in dioxan–water (1 : 1) filtered and then made up to a volume of 25 cm³, from which an aliquot was diluted 10-fold with dioxan–methanol (1 : 1) to give solution II. A standard solution of pure mangiferin (0.0100 g) was prepared in dioxan–methanol (1 : 1) (100 cm³).

Silica gel 60 F₂₅₄ plates were used and 1.0, 2.0, 3.0 and 4.0 μ L of solution II applied alongside 5.0, 6.0, 7.0, 8.0 and 9.0 μ L of the standard solution of pure mangiferin and developed with the solvent ethyl acetate–formic acid–water (67 : 13 : 20) to a distance of 10 cm. After drying, the bands were scanned for their fluorescence under UV illumination with Helena Laboratories Cliniscan densitometer and quantification followed from the peak areas obtained by integration. In a similar way, using standard solutions of colladin and colladonin alongside solutions of the natural extract with the solvent benzene–methyl ethyl

Determination of the Flavan, Catechin in Cube Gambir, from *Uncaria gambir*

Cube gambir, which is obtained industrially by drying the aqueous extract of twigs and leaves of *Uncaria gambir*, has uses in dyeing and tanning, as an astringent and more recently for its antiulcer activity attributed to its component catechin, (2R,3S)-(+)-3,3',4',5,7-pentahydroxyflavan, a compound with resorcinol and catechol structural groupings. It has to be distinguished from black catechu, which contains (2R,3S)-(-)-epicatechin and for its analysis TLC and HPLC methods have been evaluated.

With commercial HPTLC plates of silica gel 60 F₂₅₄ and the solvent chloroform-ethyl acetate-formic acid (50:40:10), catechin (*b*R_F 34) and epicatechin (*b*R_F 40) are separated, although some decomposition was detected in prolonged experiments. By using cellulose F with the solvent, 1-butanol-acetic acid-water (40:10:50, upper phase taken), based on earlier work, an improved separation was obtained (catechin, *b*R_F 64 and epicatechin 78) and decomposition avoided. Nevertheless, degradation can be avoided on silica gel by prompt development after spot application. The pure standards catechin, epicatechin and 4-hydroxybenzoic acid were used in aliquots of 1 μ L alongside 1 μ L applications of the crude extract of cube gambir which was first dissolved in methanol-water (1:1) containing 1% acetic acid and filtered. After development to 10 cm, and evaporation of the solvent, bands were detected by UV irradiation at 277 nm and measured with a Shimadzu high speed TLC scanner CS-920.

From linear calibration plots of area/concentration and six determinations based on the integrations of 18 spots, cube gambir was found from the TLC method to contain $48.21 \pm 1.6\%$ catechin compared with $50.59 \pm 0.58\%$ by HPLC. The difference of approximately 2.4% was attributed to incomplete separation by HPLC and TLC densitometry was concluded to be useful for rapid analysis and for industrial monitoring.

Table 11 Comparison of percentage compositional analyses of natural cashew nut-shell liquid (*Anacardium occidentale*) by different method

Method	Anacardic acid	Cardol	2-Methylcardol	Cardanol
HPLC	71.65 ± 0.493	22.17 ± 0.398	1.08 ± 0.049	5.13 ± 0.374
GC	71.51 ± 0.230	22.34 ± 0.110	2.75 ± 0.720	3.27 ± 0.110

Determination of Phenolic Acids in Plant Materials

Phenolic acids occur widely in combined form as esters or glycosides and for their liberation and subsequent quantitative distribution in the plant kingdom, enzymic and basic hydrolysis have been employed. Generally, comparable results are obtained by these two procedures. In the basic method the recovered phenolic acids are percolated in aqueous solution through a polyamide column and then eluted to obtain all the phenolic acids except salicylic acid and gentisic acid which are eluted with methanolic ammonia. The main phenolic acids are recovered with ethyl acetate, concentrated and made up to volume in methanol (10 cm³, solution A) and the material recovered with methanolic ammonia is similarly treated and made up in methanol (10 cm³, solution B). The method is an 'off the plate' procedure with quantification by UV spectrophotometry and absorbance at the optimum wavelength compared to the absorbance of pure reference solutions.

Silica gel G was used with solvent 1 (dichloromethane-acetic acid-water: 2 : 1 : 1) for the phenolic acids have one hydroxyl group while solvent 2 (benzene-acetic acid: (45 : 4) was used for phenolic acids with hydroxyl and methoxyl groups and for salicylic acid. Application of known volumes of A and of the standard mixture on one plate was followed by development with solvent 1 and likewise solvent 2 was used with B and the standards on another plate. After drying, the chromatograms bands are detected by examination under UV light and by spraying with methanolic ferric chloride. It was found convenient and satisfactory in practice to cover the portion of the

plate devoted to the unknown phenolic acids (A or B) and to spray the identification band with ferric chloride. The phenolic acids in the bands from the unknowns A or B were then marked out, removed by scraping, eluted with methanol and made up to volume for spectral examination under the usual conditions. Table 13 shows the spectral and R_F values for a range of phenolic acids.

For quantification, concentration/UV absorbance plots for each phenolic acid were obtained.

Determination of Chloro and Nitrophenols in Water Supplies

Phenolic compounds are widespread in the environment, either from natural sources, or from synthetic operations, and thus may be present in drinking, surface or ground waters. The US Environmental Protection Agency has quoted the compounds 2,4-dimethyl-, 4-chloro-3-methyl-, 2-chloro-, 2,4-dichloro-, 2,4,6-trichloro-, 2-nitro-, 4-nitro-, 2,4-dinitro-, 4,6-dinitro-2-methyl- and pentachlorophenols as priority pollutants. German drinking water regulations call for a limiting value of 0.0005 mg L⁻¹, while in the World Health Organization recommendations for drinking water, maximum standard values are fixed at 0.0001 mg L⁻¹ for total chlorophenols. A comprehensive examination of the TLC properties of 39 phenols on aluminium-backed RP-18 F₂₅₄ plates in 12 solvent systems has served as a basis for the detection of significant phenolic pollutants in water supplies.

Water is spiked with the phenols at a concentration of 1 mg L⁻¹ (0.0001%), adjusted to pH 2, and then sucked under vacuum through a small pretreated LiChrolut EN column over a period of 3–4 h. The column is dried with a stream of nitrogen for 15–30 min, and the phenols eluted with ethyl acetate (2 × 0.5 cm³) and made up to 1 cm³ with ethyl acetate. Samples of 2 µL are applied on to silica gel 60 F₂₅₄ RP-18 plates (10 × 20 cm) and developed with dichloromethane-*n*-hexane (50 + 50, w/v) for 20 min. Detection is by UV absorbance at 224 nm with a Camag TLC/HPTLC Scanner II. Figure 10

shows the chromatogram obtained with a mixture of five phenols (hR_F values given in brackets), 4-nitrophenol (4.7), 4-chloro-3-methylphenol (16.8) 2,4-dimethylphenol (21.9), 2,4-dinitrophenol (27.1) and 4-nitrophenol (60.3). Their visual and spectral detection limits and recoveries from the column extraction process are shown in Table 14 along with some values of other phenols which have been similarly processed.

Derivatization of phenols has also been employed to obtain the enhanced absorbance resulting from the

formation of coloured derivatives, although the resolution of the resultant compounds may then be diminished.

Conclusions

Although the TLC separation of phenols is well established for qualitative analysis, it is clear that excellent quantitative analysis can be achieved with the vast range of solvent systems, commercial plates and detection equipment currently available. HPTLC and

Figure 10 Separation of five phenols (extracted from spiked water) on silica gel RP-18 with UV detection. (Reproduced with permission from Bund *et al.*, 1995.)

RP approaches will extend the range of separative possibilities. Layers impregnated with silver and with other inorganic ions afford the opportunity for selective separations of unsaturated constituents of alkenylphenols and *cis/trans* isomers and of benzenoid compounds respectively. Combination of TLC with other chromatographic and/or spectroscopic techniques 'on' or 'off the plate' is likely to offer an economic approach to the analysis of complex mixtures of synthetic and natural phenols.

Organisms are able to communicate with each other by means of signal chemicals, or semiochemicals. These are chemicals mediating interactions between individuals, either within the same species (pheromones) or from different species (allelochemicals). Semiochemicals have been most extensively studied for insects, particularly social insects and insects of economic importance. The study of semiochemicals, and the interactions they mediate, is part of chemical ecology and contributes to the understanding of behaviour, development and evolution of organisms.

Semiochemicals are classified according to the relationships between the organisms involved. Pheromones are secreted and released by an organism and cause a specific response in a receiving organism of the same species, whilst allelochemicals are produced by one species and cause a response in a different species. Allelochemicals are further subdivided into allomones, kairomones, synomones and apneumones. Allomones elicit a response that is favourable to the emitter (e.g. defensive secretions utilized against enemies), kairomones favour the receiver (e.g. chemicals that attract parasites or predators), synomones are beneficial to both the emitter and receiver (e.g. floral scents that attract pollinators) and apneumones arise from a nonliving source (e.g. rotting meat odours).

In insects, pheromones are usually produced in specialized glands and perceived by sense organs on the antenna. Their existence has been known since early times. In 1914, the eminent French naturalist and entomologist Fabre reported that a single female of the emperor moth, *Saturnia pavonia*, kept in a wire cage on a window sill, was able to attract a great number of males from kilometres away. However, the first identification of a pheromone was only achieved in 1959. The work was started in 1939 and required the isolation of tens of thousands of excised pheromone glands before the pheromone structure of bombykol [(E,Z)-

10,12-hexadecadien-1-ol] was finally identified. Since then, improvements in isolation and identification techniques have made pheromone identification a simpler and faster procedure, utilizing only a few insects. A large number of pheromones have now been identified for organisms ranging from algae to primates.

Most pheromones fall into three main groups: sex pheromones that influence mate location and courtship behaviour; alarm pheromones that warn neighbours of impending danger; pheromones that influence spacing patterns, e.g. aggregation pheromones. Some pheromones derive specificity from their molecular structure. However, many contain compounds that are common to pheromones from different species or are components of other semiochemical systems. In these cases, specificity can be achieved by employing mixtures having unique relative proportions, with spatial or temporal separation of the organisms often adding to specificity. Although it was thought initially that pheromones would be single components, it is now clear that most are multicomponent systems and that, in many cases, behavioural effects are not mediated by the pheromone alone but require the presence of other semiochemicals. Thus, aggregation of bark beetles on a suitable host tree is mediated by a complex of semiochemicals derived from conspecifics attacking the tree, and from secondary metabolites released by the tree itself.

Structures as simple as ethanol can be employed as pheromone components. However, within the constraints required for aerial transport, considerable specificity can be achieved within one empirical formula by a combination of structural isomerism and stereoisomerism, encompassing both optical and geometrical isomerism. Thus, for the lepidopterous sex pheromones, where the basic structures usually comprise only C₁₂–C₁₆ straight carbon chains with functionalities of alcohol, aldehyde and acetate, considerable diversity is obtained by a combination of the position, degree and geometrical isomerism of unsaturated double bonds.

Insect pheromones can employ a range of structures, from fatty acid-based components to polyketides and polyisoprenoids (Figure 1). Polyketides can be simple compounds, for example 4-methyl-3,5-heptanedione (Figure 1, structure 1) the aggregation pheromone of the pea and bean weevil, *Sitona lineatus*, or structures with several chiral centres such

Figure 1 Diversity of structures employed as pheromones. **1** The aggregation pheromone of the pea and bean weevil (*Sitona lineatus*); **2** the sex pheromone of the Japanese beetle (*Popillia japonica*); **3** the aggregation pheromone of the pine engraver (*Ips pini*); **4** the aggregation pheromone of a number of pine beetles; **5** and **6** the sex pheromone of many aphid species.

as *exo*-brevicommin (Figure 1, structure 4), a component of the aggregation pheromone of a number of bark beetles, including the mountain pine beetle, *Dendroctonus ponderosae*. Simple terpenoids can also be employed, for example (*E*)-citral in the Nasonov pheromone of the honeybee, or highly chiral cyclopentanoid structures comprising the sex pheromones produced by sexual female aphids. For many aphid species, two biosynthetically related compounds are involved, a nepetalactol and a nepetalactone. There are 16 and 8 possible isomers respectively, but only the (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol (Figure 1, structure 5) and the (4*aS*,7*S*,7*aR*)-nepetalactone (Figure 1, structure 6) are behaviourally active.

Isolation Techniques

This is a key stage in the identification of semiochemicals and the techniques used will determine, to a large extent, the subsequent analytical techniques, particularly in terms of sample introduction into the gas chromatograph (GC). Most of the insect pheromones so far identified have been extracted using solvents with a range of polarities and were obtained from whole insects, specific parts of insects (e.g. pheromone glands) or the frass (i.e. the refuse and excrement) produced by feeding insects. In some instances, the pheromone is released from a droplet which can be readily collected. For example, matur-

ing eggs of the mosquito *Culex quinquefasciatus*, a vector of the parasite responsible for the tropical disease filariasis, produce a droplet containing a volatile oviposition pheromone that attracts gravid females of the same species to lay eggs nearby. In this case, sample preparation is a simple matter of collecting the droplets in a fine capillary tube. Extracts made from whole insects or pheromone glands are able, in most cases, to provide a sample containing the compounds present in the pheromone gland, but may show qualitative and quantitative differences from the naturally emitted semiochemical blend. Ratios are a fundamental aspect of many semiochemical systems. For a number of aphid species, the sexual females (oviparae) attract winged males by releasing a sex pheromone from porous plaques on their hind tibiae. Using solvent extraction of the female tibiae, it was demonstrated that the sex pheromone of the vetch aphid, *Megoura viciae*, comprises a synergistic mixture of the monoterpenoids (4*aS*,7*S*,7*aR*)-nepetalactone and (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol. However, with an air entrainment technique, collecting volatiles from the air above calling oviparous *M. viciae*, it was found that the nepetalactone was released in significantly higher concentrations than was found in the leg extracts (Figure 2). Whilst only a small amount of the nepetalactone (1–2 ng per aphid) was obtained from the leg extract, the amount produced by calling females was 200 ng per aphid.

Figure 2 GC of pheromone components produced by sexual female aphids (oviparae): amounts obtained by air entrainment and (inset) solvent extraction of excised hind tibiae.

These findings suggested that, during calling, production of nepetalactol is continuous and that a proportion of the nepetalactol is sequentially oxidized to nepetalactone. These two compounds, in different ratios, were shown to be the main components comprising the sex pheromones of many aphid species.

The problems associated with solvent extraction can be overcome by using dynamic entrainment systems, where the organism emitting the semiochemicals is contained in a glass chamber through which is passed a stream of highly purified air. The volatiles produced are swept from the system and collected in a trap, usually a porous polymer, activated charcoal or a cryogenic trapping system. They can then be recovered from the trap by either solvent or thermal desorption. The advantages of using such a system are that not only are the semiochemicals isolated in the proportions emitted by the organism, but also the extracts obtained are free from contaminants associated with straight solvent extraction and are thus directly amenable to analysis by GC. In addition, since the sampling is not destructive, it can be used to investigate the time course of semiochemical production.

Solid-phase microextraction (SPME) is a relatively new isolation technique that has been developed for the extraction and concentration of a wide range of volatile and semivolatile organic compounds from various matrices such as air, water and soil. The technique can be utilized for direct immersion into liquid samples and for sampling the headspace of liquid and solid samples. SPME uses a polymer-

coated fibre to absorb chemicals from the matrices, relying on a three-phase equilibrium between the sample, its vapour and the fibre. Samples are desorbed from the SPME fibre by thermal desorption in the GC injector. A number of fibres have been produced using different types of coating, e.g. polydimethylsiloxane (100 μm) for volatile chemicals, carbowax/DVB for alcohols and other polar compounds and polyacrylate for semivolatile compounds. Although the technique is still in a developmental stage, its ability to collect insect pheromones has already been demonstrated. However, SPME is not without its drawbacks, particularly when used for quantification, since adsorption on to the fibre is related to the chemical properties of the compound, with some compounds being adsorbed more readily than others. The time needed for a compound to equilibrate with the fibre is related to the structure of the compound, and experimental conditions such as temperature and humidity can affect the adsorptive capacity of the fibre. Despite these limitations, SPME has several major advantages in that it is rapid, nondestructive and allows sequential samples to be taken.

Sample Introduction

Analysis of complex samples places a great demand on the inlet (injection) system of the GC. The injection techniques used in capillary GC are split/splitless, direct, cold on-column and temperature-programmed vaporization. Considerable emphasis has been placed upon developing improved sample introduction techniques, minimizing sample de-

composition or isomerization, and the delivery of all components of the sample into the column in the same proportions as in the original mixture. Cold on-column injection techniques, where the sample is introduced directly on to the capillary column, can largely overcome these problems. However, this imposes considerable constraints on the initial isolation techniques, since it is essential that the sample is free from high molecular weight contaminants. Another versatile and popular technique is programmed-temperature vaporization, where the sample is introduced into a cold injector port followed by a rapid temperature rise, thus achieving vaporization.

The use of solvents can present problems for the chemical ecologist. Even highly purified solvents, when analysed on a modern high efficiency capillary GC system, show considerable levels of impurities. In addition, very volatile components can be masked by the solvent peak. Hence, in many cases, especially when working at extreme sensitivities, it is preferable to work with solvent-free systems and a number of injection systems for this have been developed. Although many were initially designed for use with packed columns, there is no fundamental difficulty in adapting them for use with capillary GC. In one of these solid sample injection systems, the material to be analysed is sealed inside a glass capillary, which is then placed inside the heated injector for a few minutes to allow the sample to volatilize, or for a biological sample to heat through. The tube is then crushed with a plunger and the volatile material is swept directly on to the column by the carrier gas. The advantages of this technique are simplicity of operation, reduced chance of contamination and no dilution. Even highly volatile compounds such as methanol and acetaldehyde can be recognized and quantified.

Thermal desorption provides another method of introducing samples on to the GC column without the use of solvents. Volatiles collected by dynamic air entrainment systems on to porous polymer traps can be removed either by solvent elution, or by thermal desorption in the GC injector. In the latter instance, all of the sample is introduced on to the GC column, thus increasing sensitivity and allowing analysis of compounds with short retention times. However, thermal desorption is not without its own drawbacks, particularly the thermal instability of some compounds.

GC Columns

Modern capillary GC columns have great resolving power and offer a high speed of analysis, greater sensitivity and the capacity to elute a greater range of

components, providing that the molecules of solute to be analysed are thermally stable, inert in terms of reacting with the capillary column and have sufficient volatility. As with all GC analyses, the most important parameters to be considered in selecting the best column are the stationary phase, internal diameter, film thickness and length. The stationary phase used in the column has the greatest effect in separation. Depending on the chemical properties of the compound, some compounds separate better on some stationary phases than on others. However, since semiochemical analyses are usually performed on complex mixtures comprising compounds with a wide range of boiling points and functionalities, the choice of column is frequently a compromise. This is not usually a problem since the high efficiency of modern capillary columns ensures that most analyses can be performed on a limited range of phases. Indeed, the stationary phases most commonly used in pheromone research are nonpolar (e.g. 100% polydimethylsiloxane), polar (e.g. polyethylene glycol) or medium polarity (e.g. poly[diphenyldimethylsiloxane] copolymer). GC columns with polar phases are invaluable for the separation of many pheromones, particularly fatty acid-derived lepidopterous pheromones.

Animal – and particularly insect – olfactory receptor systems are highly specialized and are frequently able to distinguish between enantiomers. Thus, in human olfaction, the two enantiomers of carvone (*p*-mentha-6,8-dien-2-one), a chiral cyclic ketone with one asymmetric carbon atom, have very different odours. One has the odour of caraway [(*R*)-carvone] and the other of spearmint [(*S*)-carvone]. Chirality plays a key role in insect chemical ecology and biological activity is often dependent on the enantiomeric composition of a chiral compound, and situations exist where the ‘non-natural’ enantiomer is inactive or, more problematically, may even elicit a repellent response. Japonilure, the female-produced sex pheromone of the Japanese beetle, *Popillia japonica*, comprises (*R*)-(Z)-5-(1-decenyl)dihydro-2-(3*H*)-furanone (Figure 1, structure 2) and males require high enantiomeric purity of the (*R*)-isomer to be attracted to the sex pheromone. However, males also possess receptors for the (*S*)-isomer which, when perceived simultaneously with the (*R*)-enantiomer, has an inhibitory effect, and only a few per cent of the wrong enantiomer can inhibit the response to the natural pheromone. Geographical variation in the production of, and response to, the enantiomers of the aggregation pheromone ipsdienol (Figure 1, structure 3) has been demonstrated for the pine engraver, *Ips pini*, in eastern and western populations in the USA. Thus, determination of the chirality of such

pheromones is of paramount importance in chemical ecology. However, until recently, such determinations have been limited to the sampling of large numbers of insects for determination of optical rotation by conventional methods, e.g. Fourier transform nuclear magnetic resonance.

GC techniques are preferred for enantiomer composition studies since they are very sensitive, require less sophisticated instrumentation and can be applied even to small amounts of impure biological samples. Chiral GC phases, where optical resolution is achieved through reversible diastereomeric association between the chiral environment and the solute enantiomer by means of molecular interactions such as hydrogen bonding, inclusion phenomena, transition metals or charge transfer interactions, have been used for the determination of the enantiomeric composition of pheromones. One class of widely distributed pheromone components are the spiroketals isolated from various insects such as bees, wasps and beetles. The first such pheromone to be identified was chalcogran, or 2-ethyl-1,6-dioxaspiro(4,4)nonane, the pheromone of the beetle *Pityogenes chalographus*, which was resolved by complexation GC with a capillary column coated with nickel(II)-bis(6-heptafluorobutyl)-(R)-pulegonate.

Although some chiral columns, e.g. the cyclodextrins, are now available commercially, they are relatively expensive and column performance can deteriorate quite rapidly. A convenient and attractive alternative to the direct separation of enantiomers is the GC separation of a diastereomeric derivative formed with an optically pure derivatizing agent, on achiral stationary phases which are less expensive and more generally available. A number of derivatives are available, particularly for alcohols, of which some of the most effective are the *N*-trifluoroacetyl (*S*)-alanyl esters, *N*-trifluoroacetyl-(*S*)-prolyl esters and (*R*)-*trans*-chrysanthemoyl esters. Using the latter derivatives, it is possible to obtain baseline separation of the chrysanthemate esters of 3-octanol on a simple OV-1 column. With highly purified reagents, it is possible to convert chiral alcohols and latent alcohols into separable diastereomers, enabling chiral determinations to be made on unpurified extracts of individual insects. Information on variation of pheromone chirality may have profound implications, both for population studies and for investigating the impact of pest management programmes.

Detectors

There are many types of detectors used in GC which have different degrees of selectivity. Of these, the flame ionization detector (FID) gives a response for

almost all carbon-containing compounds. Allied to this, it is rugged and relatively insensitive to operating variables and has a low dead volume and an extremely wide linear range of response. These properties have ensured that it is by far the most commonly used of all detectors in chemical ecology. Another widely used detector is the mass spectrometer and, indeed, advances in understanding the subject have been achieved largely as a result of developments in this field.

GS-mass spectrometry (GC-MS) is now the method of choice for initial semiochemical identification and, in many instances, is the only technique available and able to provide structural information at the very low sample levels usually encountered in such studies. Mass spectrometers can range from sophisticated instruments with a variety of soft ionization techniques, very high resolving power and extended mass ranges, to small bench-top instruments with limited mass ranges and other capabilities. GC-MS can also be used in quantification and selected ion monitoring (SIM) is a widely accepted quantitative technique based on monitoring the ion abundance of selected m/z values. The sensitivity of SIM for a given compound may be 1000 times as great when monitoring selected ions as when scanning the complete mass spectrum.

In addition to the universal detectors, a number of selective detectors are used. Typically, the extracts obtained from insect or plant sources may contain several hundred components, the vast majority of which are not behaviourally active. The location of the active components in such cases presents a considerable problem for chemical ecologists. This was often attempted in the past by preparative GC of the sample, followed by testing of each of the fractions in a laboratory behavioural assay. By repetitive fractionation and bioassay, it was hoped that fractions containing a single active compound could be obtained for subsequent identification studies. However, this procedure was exceedingly time-consuming and, since many pheromone systems comprise more than one compound, often fruitless. Thus, considerable efforts have been directed towards the development of selective detectors that can be coupled directly to the GC to allow rapid location of biologically active components in complex natural product extracts.

Insects perceive volatile semiochemicals via olfactory receptors, usually located on the antenna. These olfactory cells are extremely sensitive and are tuned to the detection of semiochemicals involved in the insect's chemical ecology. When stimulated, these receptors transform the chemical signal into a series of electrical events which are then passed directly to the

Figure 3 The coupled GC–electrophysiology system. (A) Antennal detector; (B) GC detector. EAG, electroantennogram; SCR, single-cell response.

insect's central nervous system. By placing electrodes in the antenna, it is possible to record these electrical events. At the simplest level, this can be achieved by excising the antenna and suspending it between two electrodes connected to an amplifier system. The so-called electroantennogram, obtained from the antenna on stimulation with an appropriate semiochemical, can then be displayed on an oscilloscope, chart recorder or computer screen. At a more sophisticated level, the responses from the individual olfactory neurons on the antenna can also be recorded (single-cell responses). These electrophysio-

logical preparations have a relatively long lifetime, ranging from tens of minutes to several hours, and thus offer considerable potential for the development of highly specific GC detectors. By linking these preparations to high resolution gas chromatography, i.e. splitting the effluent from the GC column and presenting it simultaneously to the FID of the GC and to the antennal preparation (Figure 3), it is possible to locate biologically active compounds even within highly complex extracts. Since modern high resolution GC columns typically have peak widths of only a few seconds, considerable care must be taken to ensure

Figure 4 Coupled GC–electroantennogram and GC–behavioural assay with males of the aphid parasitoid *Praon volucre*. Upper trace: GC of volatiles from virgin females; middle trace: electroantennogram response from one male; lower columns: behavioural responses (number of males, out of five tested, showing wing-fanning activity).

that components eluting from the column arrive simultaneously at the two detectors.

Coupled GC-electrophysiological techniques have provided a powerful tool in the chemical ecologist's armoury, enabling accurate targeting of specific peaks for subsequent identification by GC-MS. Indeed, the accuracy of these systems is such that, even where no GC-MS peak is observed, it may still be possible to extract sufficient information from the MS data system to allow a tentative identification to be achieved. By adding marker peaks to the sample that elute either side of the electrophysiologically active component, or by using other compounds present in the original sample which show up on the GC-MS trace,

the researcher can pinpoint accurately the region in the GC-MS chromatogram where the electrophysiologically active peak should elute. Manual interrogation of the data system can then identify specific ions that peak at the expected scan numbers. Such identifications, on picograms of material, would not be possible without the accurate information on where to look in the chromatogram that is provided by coupled GC-electrophysiological studies.

Although electrophysiological activity of a compound suggests that it is involved in some aspect of the insect's chemical ecology, it gives no indication of the behavioural role. Confirmation of the behavioural relevance of a particular component in the chromato-

Figure 5 Reaction chromatography. Bromination of alkenes. (A) Gas chromatogram of the Dufour gland contents of the ant *Myrmica rubra*, obtained using solid sampling technique with a packed column (2.75 m \times 4 mm of 10% polyethylene glycol adipate on gas chrom M.). gram can be obtained by linking the GC to a simple behavioural assay, for example the wing-fanning response elicited from male aphid parasitoids by the female sex pheromone (Figure 4). By monitoring the responses of individuals or groups of insects in the bioassay chamber as they are exposed to the effluent from the GC, it is possible to locate, quite accurately, the elution time of the semiochemical. This technique was widely used in the 1970s, particularly in studies on lepidopterous sex pheromones. More recently, this approach has been used to investigate the role of learning in mixture recognition by foraging honeybees.

Reaction Gas Chromatography

GC-MS is the main identification tool for chemical ecologists, but frequently does not provide sufficient information for a full characterization of the compounds of interest. Thus, in terms of lepidopterous sex pheromones, which usually comprise long chain fatty acid derivatives with varying degrees of unsaturation, MS frequently cannot locate the positions of double bonds, nor distinguish between (*Z*)- and (*E*)-isomers. Microscale reactions conducted before chromatography, or even on-column, can be used to provide information about the class of compound and its functional group, or even to convert them into more stable derivatives. It is possible to carry out a surprising number of reactions on nanogram quantities of material where the reaction is reproducible, quantitative and gives simple products. Various methods have been described for hydrogenation, ozonolysis, epoxidation, reduction, hydrolysis and esterification on nanogram sample levels, or even the use of subtraction loops or specific reactions to remove particular classes of compounds from the mixture (Figure 5).

Conclusions

For the chemical ecologist, GC is not just a technique that enables high resolution and separation of

complex natural product extracts. It can also provide considerable structural information. At the simplest level, noting the retention times of compounds of interest on polar and nonpolar stationary phases can give information on the molecular mass and polarity of a compound. However, when appropriate microscale reactions are included in the repertoire, the GC can prove to be a considerable aid in the identification of semiochemicals. When combined with MS, the availability of structural information is increased considerably.

Thin-Layer (Planar) Chromatography

E. D. Morgan, Keele University, Staffordshire, UK

Copyright © 2000 Academic Press

Thin-layer chromatography (TLC) in the study of pheromones is more a subject of potentials than of

wide application. Its use, some examples of its application in general and specific problems, and some sources where the reader can find procedures to follow are described here.

There is a constant argument between those who advocate simpler methods and techniques (often the

older practitioners) and those (sometimes the younger scientists) who believe that the latest and most elaborate and expensive equipment gives the best result in the shortest time. TLC lies in the thick of this argument. Its inherent simplicity, low cost, rapidity and ready interpretation are among its great advantages. Its detractors draw attention to its limited resolution and relatively poor limit of detection. Nevertheless, it is a useful and time-saving technique, worthy of consideration, and there are several recent books devoted entirely to the subject. The technique can be very simple, with hand-applied mixtures and simple spectroscopic, chemical or just bioassay detection methods, or it can be as instrumentally complex as one wishes, with automatic application, scanning densitometers, linking to nuclear magnetic resonance (NMR) and mass spectrometers. A new automatic device is available for collecting bands of silica from a TLC plate and transferring them by suction to solid-phase extraction (SPE) cartridges, which are then extracted with solvent.

Wilson has done much to show the capabilities of TLC allied to other techniques. Modern NMR spectroscopic methods make it possible to place the silica band containing the compound of interest directly into the NMR tube and obtain high resolution spectra. Mass spectroscopists were reluctant at first to put fine silica powder from TLC plates directly into their instruments but now commercial devices are available for doing just this. Highly polar compounds are not suitable for electron ionization-mass spectrometry (EI-MS) by direct insertion of the silica band from TLC, but several groups have shown that fast atom bombardment-mass spectrometry (FAB-MS) can be performed directly on this material, and that with suitable instruments, fragmentation information can be obtained by thin-layer chromatography-tandem mass spectrometry (TLC-MS-MS). Fell has written a comprehensive review on TLC in the study of insects (divided into carbohydrates, lipids, ecdysteroids and terpenoids, amines and pigments). Advocates of TLC, however, have not had a great influence on the field of pheromone studies, but TLC can have great advantages in preliminary studies of new pheromones.

Whatever one places on a TLC plate can be recovered (provided it does not decompose in the meantime), but with both gas chromatography (GC) and high performance liquid chromatography (HPLC) compounds can be either lost in the solvent front or never eluted from the column. Without a good quantitative bioassay or the use of radio-labelled samples the loss would not be detected and the research would be defective. With a simple bioassay, TLC can quickly yield information. An example from personal experience is illustrative. At the beginning of a study of the

Structure I

trail pheromones of *Myrmica* ants, no candidate peaks could be seen in a GC of an extract of the glands. To make sure the material was stable enough to purify, several poison glands known from bioassays to be the source of the pheromone were placed at the origin of a TLC plate, and chromatographed with hexane-acetone (7 : 3). Then the silica from the origin to the solvent front was divided into several bands, which were scraped from the plate, and eluted with acetone or methanol and the extracts submitted to a simple bioassay. There was far too little material there to be visualized by a chemical test. The active band containing the pheromone was readily recognized by a positive bioassay; the other bands were inactive (Figure 1). There was no correlation evident between activity and visualized bands because there was so little of the pheromone present. By trying a few other solvent systems, a good idea of the polarity of the pheromone was quickly obtained. By a few further TLC experiments (adding NaBH₄, NaOH or HCl) it was quickly established that the substance did not contain a reducible ketone group, was not acidic, but was basic. This knowledge greatly encouraged and simplified the subsequent isolation and identification of the pheromone (3-ethyl-2,5-dimethylpyrazine; structure I) with GC-MS. A little chemical imagination can devise other simple reactions that can be used with TLC to learn about functional groups. Once the simple TLC with bioassay has been mastered, more advanced techniques suggest themselves.

Insects

Since many pheromones are readily volatile and transmitted through the air, gas chromatography has been the technique of first resort. It is too often forgotten that some pheromones are not volatile. A good example of a totally involatile pheromone is the oviposition-deterrent pheromone (structure II) of the cherry fruit fly *Rhagoletis cerasi*, identified by a large group led by Hurter, and for which a great deal of TLC was used.

When the female fly lays her egg inside the cherry, she places the pheromone on the cherry surface to warn other flies that this cherry is already occupied. It must remain there for the life of the larva, and withstand sunlight and rain. Isolation began with 7.3 g of female fly faeces, extracted with methanol and

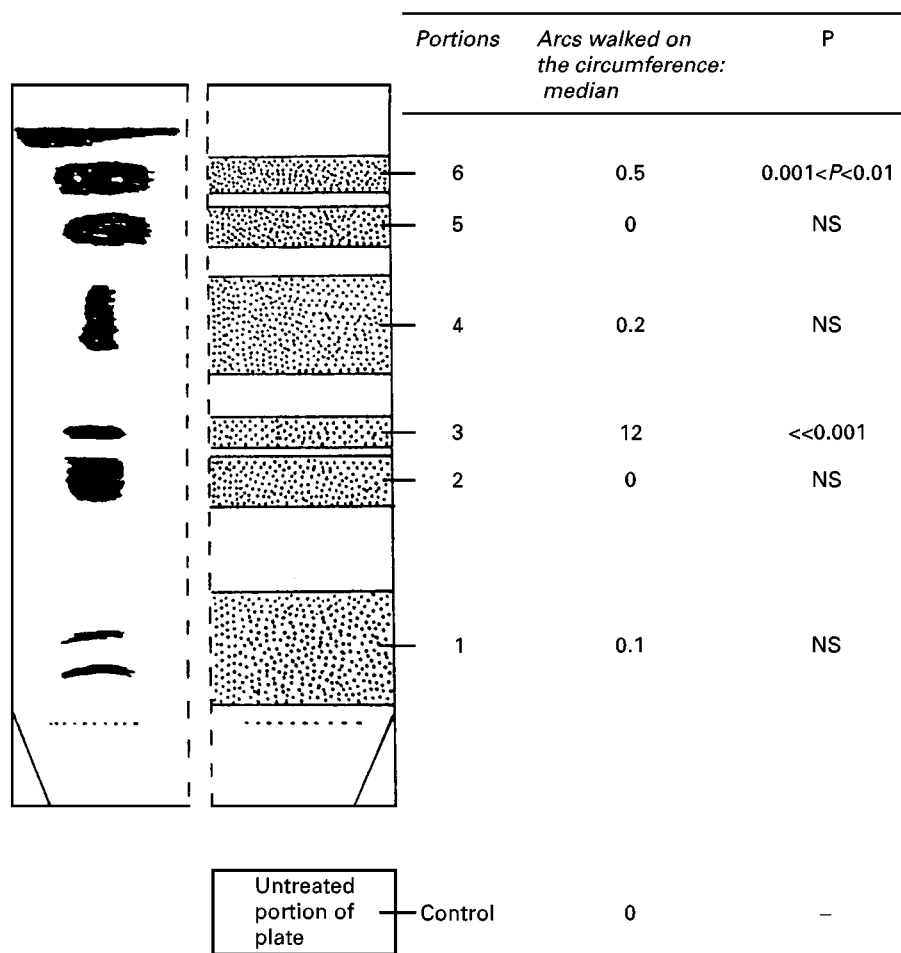

Figure 1 Thin-layer chromatogram of poison glands of *Myrmica rubra* ants applied to the origin of a silica plate and eluted three times with hexane–acetone (85 : 15). The plate was partly sprayed with phosphomolybdic acid for visualizing, and partly cut and the silica removed for elution of activity as shown. The activity of the fractions as indicated by worker ants following a circular trail is also shown. *P*, Level of probability; NS, nonsignificant difference for $P = 0.01$. (Reproduced with permission from Cammaerts-Tricot *et al.* (1997) Isolation of the trail pheromone of the ant *Myrmica rubra*. *Journal of Insect Physiology* 23: 421.)

cleaned up on a cellulose powder column. Preparative TLC on PSC cellulose, developed with ethanol–water (1 : 1), and cutting 0.1 R_F bands located all the activity in the 0.9–1.0 R_F band. This was subjected to HPLC and the active band was further separated on Antec OPTI-UP C-12 plates, developed with methanol, and the activity was found this time in the 0.5–0.7 R_F band. Later, when the pure pheromone was obtained, the taurine fragment was identified by

TLC on Merck Silicagel 60F₂₅₄, using *n*-butanol–99% acetic acid–water (8 : 3 : 1), and *n*-propanol–25% aqueous ammonia (8 : 2) and visualizing with Cl₂, I₂ and N,N,N',N'-tetramethyl-4,4'-diaminodiphenylmethane.

The sex attractant pheromones of Lepidoptera are not stored in the pheromone-producing gland but are synthesized and released as required. Aldehydes are the immediate precursors in *Manduca sexta*, but

Structure II

Structures III and IV

to find which of the lipid classes was the source of the aldehydes, conventional lipid TLC was used effectively. Reversed-phase TLC has been used in the actual identification of lepidopteran sex pheromones too. Merck RP-8F_{254S} plates with acetonitrile–water (9 : 1) were used by Ando and others to separate C₁₂ to C₁₆ alcohols, aldehydes and acetates. Chromatograms were presented; this demonstrates how it is a useful tool in determining the chain length and number of double bonds. Separation of the *cis-trans* isomers so common in lepidopteran pheromones is very simple by argentation TLC.

Sex pheromone activity of the brown-legged grain mite *Aleuroglyphus ovatus* (strictly, mites are not insects) was not observed by Kuwahara in either a crude hexane extract or in column chromatography fractions. But when carefully separated from masking alarm pheromone activity of citral by TLC, the activity was readily recognized and the pheromone identified as 2-hydroxy-6-methylbenzaldehyde. The different pheromones of the camel tick and the dog tick were first studied by TLC, which showed them to be in the cholesteryl ester fraction of the surface lipids of the ticks, then HPLC was used to identify the exact compounds. Two-dimensional reversed-phase high performance thin-layer chromatography (RP-HPTLC) was used in the final stage of purification of a group of long chain branched and unbranched alcohols and acetates in looking for the female-produced sex pheromone of the screwworm fly, a serious pest of cattle. Plates were eluted once with hexane–ether (94 : 6) in one direction, then five times with hexane–benzene (96 : 4) in the second direction.

TLC is an excellent way to study the biosynthesis and metabolism of pheromones and precursors using autoradiography. The biosynthesis of the sex pheromone (3,11-dimethylnonacosan-2-one; struc-

ture III) of the German cockroach was studied through radio-TLC and radio-GC of a tritiated hydrocarbon precursor, 3,11-dimethylnonacosane (structure IV). When the hydrocarbon was applied to the surface of the insects, it was poorly converted to the ketone (structure III), but also to the intermediate alcohol. The alcohol, when applied, was efficiently converted to the ketone (Figure 2).

The effect of age and day length on the production of the main component ((*Z*)-11-hexadecenal) of the sex pheromone of the important grain pest *Helicoverpa zea* was quantified by TLC and GC. Radioactivity in the TLC fractions was monitored by scraping off bands of the silica for scintillation counting. Later the direct nervous control of the synthesis of this compound was demonstrated with radio-TLC, radio-HPLC and column chromatography. Further studies of the stimulation of pheromone production in glands of *H. armigera* and production of its fatty acid precursors were both measured by TLC. Similar methods were used to correlate the amounts of pheromone aldehydes and their triacyl glycerol precursors in the glands of the tobacco hornworm *M. sexta*.

Other Animals

TLC can be still more useful in the separation of the complex mixtures often encountered in mammalian pheromones. Female mole rats (blind, solitary rodents), when they are on heat, are attracted to substances in the urine of adult males which they would otherwise avoid. The urine was extracted with dichloromethane and the activity was shown by TLC to be correlated with the sterol and fatty acid ethyl ester fraction, but TLC also showed that this was only part of the activity found in the urine.

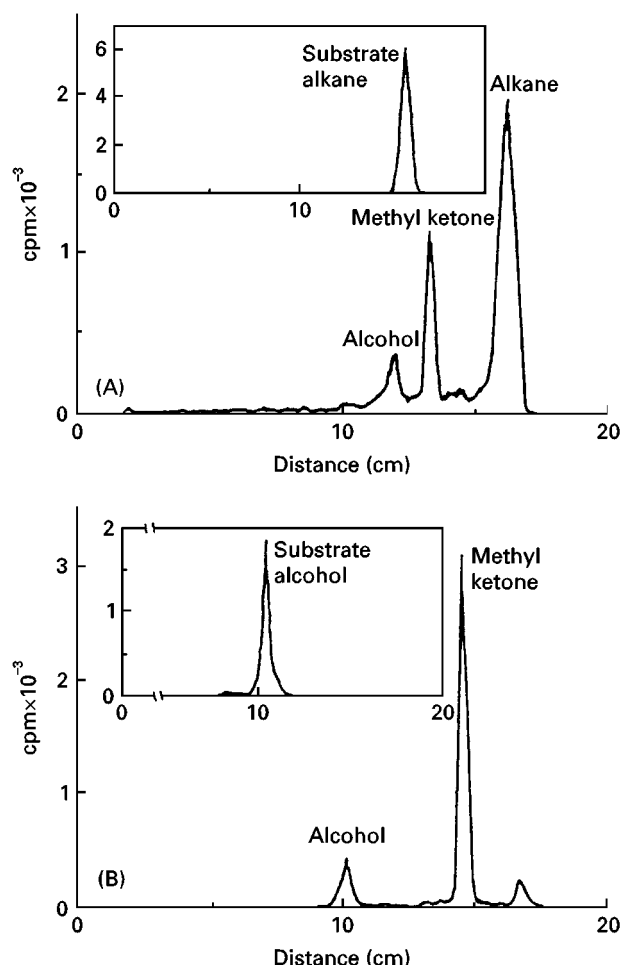

Figure 2 (A) Radio-TLC of cuticular extracts from female German cockroaches treated with $[11,12-^3\text{H}_2]-3,11$ -dimethyl-nonacosane (inset: TLC of the pure alkane used). (B) Similar TLC of products when female insects were treated with $[11,12-^3\text{H}_2]-3,11$ -dimethyl-2-nonacosanol (inset: TLC of pure alcohol used). (Reproduced with permission from Chase *et al.* (1992) Biosynthesis and endocrine control of the production of the German-cockroach sex-pheromone 3,11-dimethylnonacosan-2-one. *Proceedings of the National Academy of Sciences of the USA* 89: 6050.)

Tigers, like domestic cats, mark territory by spraying a marking pheromone upwards and backwards with their urine. The more volatile components are held from too rapid evaporation by lipid fixatives. The composition of the fixative has been studied by TLC and separated into cholesteryl esters, wax esters, tri-, di- and mono-glycerides, free fatty acids, sterols and phospholipids. The nature of the components could then be determined by transesterification and GC.

Marine Animals

Even fish pheromones have yielded to a study by TLC. The male yellowfin sculpin from Lake Baikal

releases a sexual pheromone with its milt to attract females. An ether extract of male urine was separated into fractions, much as described above for *Myrmica* ants, and the active fractions from TLC were further purified by HPLC, and mass spectrometry identified testosterone and 11β -hydroxytestosterone. A third component was probably farnesol. TLC was used similarly to identify androgens in the serum of male Australian lungfish, and showed that testosterone was the main androgen. The exploration of maturation pheromones in goldfish has been studied through metabolism of $[^3\text{H}]-17\alpha$ -hydroxyprogesterone by ovarian follicles and following the products with autoradiography of TLC plates. Even corals produce pheromones at reproduction time. The identification in, and metabolism of, $[^3\text{H}]$ progesterone and $[^3\text{H}]$ androstenedione by Antarctic soft corals was studied by TLC with multiple elution. The metabolites are thought to be part of their chemical signalling or defensive metabolites.

Enantiomers

Enantiomer identification and separation are very important in pheromone isolation and synthesis, although no example of TLC used for this purpose can be found. Lepri's review of enantiomer separation by TLC gives many examples of its use that could be applied in pheromone studies.

Concluding Comments

Everyone knows about TLC, and everyone will have used it in their undergraduate days. All the techniques are in place for the greater use of TLC in pheromone research. All that is needed is for investigators to bear it in mind. It can save a great deal of time and effort in the preliminary stages of an investigation, give some indication of the characteristics of the compound being investigated, and provide a guide to the best instrumental method for further separation or purification. Mass spectrometry has long been able to handle the material from a single TLC band; with modern NMR instruments, there can be enough material on a single plate to obtain a good spectrum. The future of TLC in pheromone work could be bright: its greatest enemy is inertia.

PHYSICOCHEMICAL MEASUREMENTS: GAS CHROMATOGRAPHY

J. R. Conder, University of Wales, Swansea, UK

Copyright © 2000 Academic Press

Introduction

Chromatography has been used for making physicochemical measurements for as long as it has been used for chemical analysis. When Martin and Synge introduced liquid-liquid chromatography in 1941 they also described how they used it to determine the distribution coefficient of the solute between the two (mobile and stationary) liquid phases.

In the early publications on gas-solid chromatography (GSC), by Wicke in 1940 and 1947 and Cremer and Prior in 1947 and 1951, the use for chemical separation is described simultaneously with physicochemical applications to the measurement of adsorption isotherms and free energies of adsorption. The earliest physicochemical measurements by gas-liquid chromatography (GLC) date from 1955 and 1956,

when several authors described how to measure boiling points, partition coefficients and heats and entropies of solution for a volatile solute dissolved in a nonvolatile solvent. Since then, the scope of gas chromatographic (GC) techniques of physicochemical measurement has branched out in many different directions and now extends into a great variety of fields. These techniques are used by chemists and chemical engineers in many different specialist areas.

It is estimated that several thousand research papers have been published to date on the physicochemical applications of GC. Some of these applications have analogues in liquid chromatography, which is the subject of a separate article (Physico-Chemical Measurements).

Types of Measurement

The different types of physicochemical properties which can be measured by GC are classified in

Figure 1 Classification of the physicochemical applications of gas chromatography. (Reproduced with permission from Conder, 1992.)

Figure 1 and listed in Table 1. They fall into three categories: equilibrium properties, kinetic and transport properties, and miscellaneous properties.

Equilibrium Properties

The largest category of properties measurable by GC is equilibrium properties obtained by measuring retention volumes. The equilibrium parameters relate to the distribution of a solute between a moving carrier gas and a stationary phase which may be liquid, solid or interfacial. (The term 'solute' is used here for all these cases.) The solute is usually injected as a small, discrete sample and its retention volume is determined. For example the activity coefficient γ of a volatile solute in a liquid stationary phase coated on an inert solid support can be determined by simply measuring the retention volume V_N of the solute and using the equation:

$$\gamma = \frac{RTW_L}{V_N p_1^0 M_L} \quad [1]$$

where R is the universal gas constant ($8.314 \text{ kJ kmol}^{-1} \text{ K}^{-1}$), T is the temperature (K), p_1^0 the saturation vapour pressure (kN m^{-2}) of the pure solute, W_L the mass of stationary phase in the column (kg) and M_L its molecular weight (kg kmol^{-1}). For the most accurate measurements this equation is modified to incorporate a gas imperfection correction.

Besides activity coefficients, other parameters describing interactions in solution can be determined from measurements of retention volume and appropriate theoretical analyses, as listed under solution

interactions in Table 1. Similarly, one can use retention measurements on suitably chosen systems of solute, stationary phase, support and mobile phase to study many surface interactions, phase transitions and physical properties of single substances, again listed in the table. A useful technique in some of these cases is inverse chromatography, where the solute is used merely as a probe to explore the behaviour of the stationary phase. This technique has been much used in investigations of polymer solutions, solid surfaces, and the various types of phase transitions listed in Table 1. Interactions between components in the gas phase are measured by varying the pressure at which the column is operated.

Kinetic and Transport Properties

Many kinetic and transport properties can be determined from the extent to which they cause a migrating solute peak to broaden as it moves along the column, or more generally from the solute concentration-time profile recorded at the column outlet. Thus, the height H (in units of length of column) equivalent to a theoretical plate can be determined by measuring the second moment σ of the peak (in time units) and the retention time t_R and using the equation

$$H = L \left(\frac{\sigma}{t_R} \right)^2 \quad [2]$$

where L is the length of the column. It is known that H varies with carrier gas velocity according to equations such as the van Deemter equation which includes parameters such as the diffusivities of the solute in the carrier gas and liquid phase and the film

thickness of the liquid phase. Consequently, these parameters can be obtained by determining H as a function of gas velocity.

Reaction rate constants are measured by several techniques. Some involve stopping or reversing the

flow through the column. Others involve determining the solute concentration-time profile at the column outlet (Figure 2).

Miscellaneous Properties

The third and last category is a miscellaneous group of properties which can be obtained from either the retention volume, the peak profile, or the area under the recorded peak. These include molecular weights, surface areas and polymer crystallinity, as listed in Table 1.

In all the categories of physicochemical measurement so far described, the property studied is derived from measurements based on the chromatographic processes occurring in the column. There are also a few types of physical measurement in which GC is used purely as a tool of chemical analysis. These are not covered in this article though it should be pointed out that, in some cases, the analytical approach is well established, e.g. in studies of the kinetics of gaseous reactions, or of vapour-liquid equilibria by headspace analysis.

Status of GC Methods

Of the three categories of GC measurement just described, the study of equilibrium properties is the largest. This area depends on the theory of chromatographic retention which is firmly founded. Equilibrium properties are usually measurable with greater precision than other GC properties. Precisions as high as 0.05% are attainable, depending on the application and the quality of the equipment used.

Figure 2 Illustration of the product curve method for determining reaction rate constants. The reaction is the decomposition of dicyclopentadiene in the liquid Silicone DC 550 at 190°C. The chromatogram is produced after a sample of dicyclopentadiene (reactant) is injected into a GLC column with Silicone DC 550 as the stationary phase. The reactant is adsorbed more strongly than the products and so elutes later. According to the theory of the product curve method the rate constant is found from the slope of a logarithmic plot of the product curve in the chromatogram. (Reproduced with permission from Langer and Patton, 1973.)

In contrast, measurements of transport properties such as diffusivities are much affected by the form of peak broadening model used to analyse the data. For instance, the original van Deemter equation has been superseded by more elaborate models whose relative merits have been much debated. Early studies of transport processes by GC were therefore mostly restricted to applications motivated particularly by the needs of GC itself, such as improving the efficiency of separation in analytical, preparative and production GC. Since then, however, the technique has also found wider application to rate measurements where it sometimes possesses singular advantages. Thus, certain forms of GC measurement of diffusivities provide some of the best diffusion coefficient data currently available. As a further example, studying reactions by conducting them in a chromatographic column offers the unique feature of simultaneous reaction and separation, allowing forward and back reactions to be studied directly without mutual interference, as shown in Figure 2.

Among methods of physicochemical measurement, GC offers an unusually wide range of application. Three particular roles may be distinguished:

- GC often provides an alternative to other techniques, with different advantages and disadvantages.
- GC has proved a fruitful means of discovery of new generalizations based on large volumes of data.
- GC can be combined synergistically with other techniques to shed new light on the phenomenon under study.

Examples of the first role are numerous. Thus, the most important concentration region for studying molecular interactions in solution is infinite dilution of the solute component. Non-GC methods, which depend on measuring vapour pressure, suffer from diminishing precision of measurement as infinite dilution is approached. The GC method, which depends on measurement of retention, is not inherently concentration dependent. Simple elution chromatography lends itself particularly well to infinite dilution, while several chromatographic methods, involving both elution and frontal modes of operation, are available to cover a wide concentration range up to a high mole ratio of solute in the mobile phase (Figure 3). As a second example, determination of mixed second virial coefficients of gas mixtures by non-GC methods, such as compressibility measurements or from pressure or volume changes on mixing, require an accurate knowledge of the second virial coefficients of both pure components. GC provides an alternative method which not only avoids this need but is more accurate.

In the second role, GC has led to the discovery of a number of valuable generalizations about the behaviour of chemical systems. For instance, it has been found that the partition coefficient of a solute in a binary mixture of two involatile liquids is very often a linear function of the volume fraction or molarity of either binary component. This has been shown to hold, with a few exceptions, for over 400 different systems (Figure 4). Similarly, studies have shown that the thermal behaviour of a variety of polymethylenic liquids spread on silica-type surfaces closely mimics their behaviour on the surface of water. This indicates the formation of orientated monomolecular films whose transitions have accordingly been explored by GC. In cases such as these, the value of GC lies in its speed and simplicity. Alternative methods, such as vapour pressure measurement or infrared, ultraviolet or magnetic resonance spectroscopy, are less practical for collecting the large volumes of data required. Another field of application is the correlation of retention with structure and pharmacological behaviour (QSRR).

Sometimes, results obtained by GC and other methods appear to differ. This has been observed, for example, in studies of phase transitions and adsorption at gas-liquid interfaces. In such cases the value of chromatography lies in the scientific progress achieved by trying to understand why different methods of studying apparently the same property give different results. By combining chromatographic, surface tension and gravimetric solubility measurements, for example, Martire, Pecsok and Purnell in 1965 were able to obtain unambiguous values of the average thickness of the liquid film on a porous support and resolve previous differences over the surface area and distribution of liquid on the support.

Advantages of GC Methods

As an alternative to other means of studying physicochemical behaviour, GC has its own advantages and disadvantages which depend on the applications concerned. However, certain characteristic advantages and disadvantages can be discerned. The principal advantages are enumerated below.

Speed

GC experiments are relatively fast. Local equilibrium is achieved very rapidly in the column because the interfacial area between the mobile and stationary phases is very large and path lengths for mass transfer are short. Solutes therefore usually pass through the column in minutes or even seconds. The virtue of speed provides many advantages. It is particularly valuable for solutes which are thermally unstable or have only short radioactive half-lives.

Figure 3 Example of activity coefficients in solution studied at finite solute concentrations: comparison of GC and static (gravimetric) results. The logarithm of the activity coefficient γ of the solute *n*-hexane in squalane stationary phase is plotted against mole fraction x of *n*-hexane at 30°C. (a) Chromatographic technique of frontal analysis (FA) using frontal breakthrough curves for: O diffuse front (sorption), ● self-sharpening front (desorption). (b) Chromatographic technique of elution on a plateau (EP) of constant solute concentration. Continuous curve: best line, extrapolated to $x = 0$, through static data of Ashworth and Everett (1960) obtained with squalane supported on Celite. Broken curve: static data of Martire, Pecsok and Purnell (1965) obtained with unsupported (bulk) squalane. The separation of about 2½% in γ for the two static plots is small but experimentally significant and is believed to be due to the use of different samples of squalane. The results of the GC techniques are in excellent agreement with each other, with the static data of Ashworth and Everett (1960) and with further static measurements by Ashworth (1973). (Reproduced with permission from Conder and Purnell (1969) *Transactions of the Faraday Society* 65: 839. Copyright Royal Society of Chemistry.)

Experimental time can often be saved by injecting a mixture of several solutes of differing retentions in one run. Work requiring large amounts of data can be conducted within a reasonable timescale.

Contact times can be kept short. When adsorption on catalysts is studied by static methods, the problem is to observe it despite the accompanying presence of decomposition. The temperature has to be far below the normal operating temperature of the catalyst to avoid excessive decomposition during the experiment. With elution GSC the temperature can be near the normal operating temperature because of the short contact time between 'solute' (adsorbate) and adsorbent at each point in the column. Low contact time is also beneficial in studying adsorption on polymer surfaces. Here static measurements do not distinguish between surface adsorption and bulk adsorption. GSC allows the rapid adsorption process

to be examined without interference from the slower adsorption process.

Small Amounts of Material Required

GC measurements at infinite dilution require only very small amounts of solute, e.g. 100 µg, but as little as 10^{-11} g can be used if necessary. This is a particular advantage for solutes that are available only in trace amounts. The amount of stationary phase needed is also relatively small – 2 g of liquid is typical in a packed column but 1 mg of liquid can be used in a capillary (open tubular) column.

Impure and Mixed Solutes

Solute mixtures or impurities are usually separated on the column, and so can be run without previous purification.

Figure 4 Example of linear plots of gas-liquid distribution coefficient K_L of solutes against molar concentration (mol L^{-1}) of di-*n*-butyltetrachlorophthalate in squalane at 80.3°C . Data of Eon, Pommier and Guiochon. The solutes are: (1) 2-methylfuran, (2) 2,5-dihydrofuran, (3) benzene and (4) thiophen. (Reproduced with permission from Purnell and Vargas de Andrade (1975) *Journal of the American Chemical Society* 97: 3585. Copyright American Chemical Society.)

Reactive Solutes

GC methods are often preferred for reactive solutes because separation of reactants and products on the column allows the forward reaction to be studied alone without interference from the reverse reaction or from autocatalysis or product inhibition. Additionally, contact times are short, quantities small and fewer difficulties are encountered with reaction with the materials of construction of the equipment.

Wide Temperature and Pressure Range

Change of temperature is much more easily accomplished in a chromatograph than in most volumetric or gravimetric techniques. Additionally, because the column is of small diameter and compact, extremes of temperature and pressure can be achieved more readily than by many other techniques, e.g. below 100 K, above 1200 K, or up to 2000 bar.

Characteristics of GC Methods

Despite the advantages of GC methods, there are also several characteristic limitations inherent in the technique which need to be appreciated for reliable

measurement. Much effort has been expended in overcoming these limitations. On the whole considerable success has been achieved, though often at the expense of complicating the technique. We will consider five characteristics of the method: interference between interactions under study, stationary phase volatility, the number of components in the system studied, the influence of the 'inert' carrier gas and the influence of the support.

Interference Between Interactions Under Study

The remarkable versatility of the method seen in Table 1 is partly due to the large number of components characteristically present in a chromatographic column. A GLC column contains at least three bulk phases (gas, liquid and solid) and two interfacial phases (gas-liquid and liquid-solid; the gas-solid interface is seldom problematic in GLC). Potentially, therefore, the study of one interaction may be complicated by the presence of another. Common examples of interfering processes are adsorption on the solid support and/or adsorption at the gas-liquid interface during studies of interactions in solution. The adsorption increases the retention volume from which the solution parameters are to be determined. Sometimes it is possible to avoid or minimize the interference by suitable choice of support. If not, procedures have been devised involving varying the loading of liquid phase on the support and plotting the data in such a way as to determine both the solution and adsorption parameters.

Influence of the Solid Support

This is the commonest example of the interference problem just described. Physicochemical measurements are usually made with packed columns. In GLC a solid support is used to hold the stationary phase as a liquid of high surface area. It is seldom safe to treat the support as completely inert. Adsorption of solute by the support often causes 'tailing' of polar solutes. It is not always appreciated that support adsorption may still affect solute retention even when no tailing is observed. Reproducibility of the support was a serious bar to reproducible data in early GC work. Support adsorption can be detected and eliminated by varying the liquid loading and analysing the data appropriately. This is a desirable procedure in all GLC measurements of solution equilibria unless there is already good evidence that adsorption by the support is negligible. It is usually found that support adsorption can be neglected with nonpolar organic solutes. In other cases one can either greatly reduce the effect by chemically reacting the support surface with a silanizing agent, or eliminate the effect by

appropriate data analysis of measurements at different liquid loadings.

Volatility of the Stationary Phase

By its nature, GC is well suited to studying binary systems involving one volatile component, the solute, and one involatile component, the liquid or solid stationary phase. The technique may be extended to volatile stationary phases with vapour pressures up to about 3 bar, either by the well-established approach of pre-saturating the carrier gas with vapour of the stationary phase, or by a technique of nonsteady-state gas chromatography recently developed for the purpose.

Multicomponent Systems

In simple chromatography with an inert carrier gas, there are often only two active components, the volatile solute and a single-component, involatile, stationary phase, together forming a binary system. Two types of multicomponent system can also be studied. In the first, there are two or more involatile components in the stationary phase. This type of multicomponent system is met in studying complexing behaviour in solution. It presents no new problems of technique though the analysis of the data is of great thermodynamic interest. In the other type of multicomponent system more than one volatile component is involved in the liquid phase interaction. In this case one of the two volatile components must be introduced at a steady concentration into the carrier before entry to the column, and the other solute is injected as a discrete sample. This method has been used to study multicomponent gas-liquid and gas-solid equilibria at high pressures.

Influence of the 'Inert' Carrier Gas

Although the carrier gas is often thought of as inert, several interactions involving the carrier and solute occur in the gas phase. The combined contribution to the measured retention of solute is of the order of 1–5%. This is usually known as the gas imperfection correction. It needs to be calculated and corrected for in studies of adsorption or solution equilibria making any claim to accuracy. The correction was often omitted or incorrectly calculated in early studies and invalid versions of the correction are still sometimes quoted in current publications.

Apparatus Requirements

Most physicochemical measurements by GC are conducted with packed rather than open tubular (capillary) columns. The very high resolution offered by

open tubular columns is of little benefit for most physical measurements. Determination of the mass of stationary phase in the column is easier and more accurate with packed columns.

The type of GC apparatus needed for physicochemical measurements depends on the precision of measurement desired, which varies with the application. A commercial instrument is often suitable for simple physical properties such as latent heats, boiling points and vapour pressures, where the role of GC is to provide a method of obtaining large amounts of data rapidly. The control of column temperature may be of high precision but poor accuracy with a commercial chromatograph, but with improved instrumentation of pressure and flow rate, is also appropriate for most measurements at infinite dilution of the solute. For work at finite concentrations of the solute, however, it is necessary either to inject especially large samples of solute or to pass into the column a steady concentration of solute in the mobile phase. Various forms of finite concentration technique have been developed. Almost all require a purpose-built instrument or a specially modified commercial unit. Studies of gas phase interactions, which entail elevated pressures, also require specially built GC equipment.

Measurement of Separation Process Data

In the design of process plant a variety of data is needed on the properties of substances, particularly in designing separation and reaction processes. Chemical engineers are not always as aware as chemists of the suitability of GC methods for obtaining property data, but the potential is considerable. Of the parameters listed in Table 1, those particularly relevant to process engineering include physical properties of single substances, activity coefficients in solution, gas solubilities, liquid-liquid distribution coefficients, multicomponent equilibria, adsorption coefficients, diffusivities, mass transfer parameters, reaction rate constants and some of the miscellaneous properties.

pH-ZONE REFINING COUNTERCURRENT CHROMATOGRAPHY

Y. Ito, National Institutes of Health, Bethesda, MD, USA

Copyright © 2000 Academic Press

What is pH-zone-refining Countercurrent Chromatography (CCC)

This countercurrent chromatography (CCC) technique distributes large quantities of ionic analytes (acids and/or bases) into a train of rectangular peaks of very high concentrations with high purity. The method utilizes ionic interaction between analytes to shift their partition coefficients according to pK_a and hydrophobicity.

Development of pH-zone-refining CCC

In liquid chromatography, isocratic elution usually produces symmetrical peaks where the peak width increases with retention time. In the course of purification of BrAcT_3 (*N*-bromoacetyl-3,3',5-triiodo-L-thyronine) by high-speed countercurrent chromatography (HSCCC), it was found that the product formed an unusually sharp peak corresponding to over 2000 theoretical plates, while the preceding impurity peak showed a normal width of about 500 plates. The cause of this sharp peak formation was

finally found when the collected fractions were manually analysed for pH. As shown in Figure 1, the pH-curve showed a gradual decline after the solvent

Figure 1 Disclosure of the cause of sharp peak formation by manual pH measurement. Sample: CCC-purified BrAcT_3 (approximately 0.1 mmol) + blank bromoacetylation mixture. The elution of the sharp peak coincides with the abrupt rise of the pH suggesting the acid in the sample solution as the cause of the peak sharpening.

Figure 2 Schematic illustration of the peak-sharpening process in the separation column. A portion of the column contains non-polar stationary phase in the upper half and the polar mobile phase in the lower half. The acid analyte circles around the sharp retainer border by repeating protonation and deprotonation as described in the text.

front followed by an abrupt rise which coincided with the elution of the sharp product peak. Mass spectro-metric analysis of the sample solution showed the presence of bromoacetic acid, a reaction product of BrAcT_3 synthesis. Here, bromoacetic acid acts as a 'retainer' acid since it prevents elution of the analyte. Other organic acids such as trifluoroacetic acid (TFA) and acetic acid also can produce this effect, if introduced in the sample solution and/or the organic stationary phase. It must not be added to the mobile phase which should instead contain a base such as ammonia which acts as an 'eluter' base in the opposite sense of the 'retainer' acid.

A portion of the separation column shown in **Figure 2** indicates that the organic stationary phase is in the upper half and the aqueous mobile phase in the lower half. As described by its non-linear isotherm, the retainer acid forms a sharp rear boundary which moves through the column at a rate lower than that of the mobile phase. When the acid analyte is present in the mobile phase at position 1 (**Figure 2**), it becomes protonated due to the low pH and partitions into the organic stationary phase at position 2. As the basic mobile phase moves forward, the analyte is exposed to a higher pH at position 3 where it is deprotonated (ionized) and transferred to the lower aqueous phase at position 4. In the aqueous mobile phase the analyte migrates quickly through the sharp retainer border to repeat the cycle. Consequently, the analyte is always confined to a narrow region around the retainer border and elutes as a sharp peak together with that border.

In order to trap the analyte peak around the retainer border, one requirement must be satisfied. In **Figure 3** K_r represents the partition coefficient (sol-

ute concentration in the stationary phase divided by that in the mobile phase) of the retainer acid, and K_a and K_b for those of the analyte at acidic and basic conditions, respectively. If K_r is greater than K_a and K_b , the analyte elutes earlier than the retainer border forming a broad peak (peak 1). If K_r is smaller than K_a and K_b , the analyte elutes after the retainer border again with a broad peak (peak 3). Peak sharpening takes place only when K_r falls between K_a and K_b (peak 2).

This method allows the use of multiple retainer acids as spacers to separate sharp analyte peaks at their boundaries. **Figure 4** shows a separation of three dinitrophenyl (DNP)-amino acids by the spacer acids. The separation was performed with a two-phase solvent system composed of methyl *t*-butyl ether/water where TFA and three spacer acids were added to the upper organic stationary phase and ammonia (eluter base) to the lower aqueous mobile phase. Polar DNP-aspartic acid (DNP-asp) was eluted between acetic acid and propionic acid, DNP-alanine (DNP-ala) between propionic acid and *n*-butyric acid, and the more hydrophobic DNP-leucine (DNP-leu) after *n*-butyric acid.

This 'pH-peak-focusing' CCC has useful applications such as the concentration and detection of minor components and the improvement of analytical separations by shifting the retention time of the analyte away from non-ionic impurities. However, the most important application is found in preparative-scale separations. When the sample size of the DNP-amino acids in the above separation was in-

Figure 3 General requirement of sharp peak formation. Peak 1 is obtained when both K_a and K_b are smaller than K_r , while peak 3 is obtained when both K_a and K_b are greater than K_r . Sharp peak 2 is formed when K_r falls between K_a and K_b , as indicated above.

Figure 4 Separation of DNP-amino acids by spacer acids. Three spacer acids introduced in the stationary phase form pH-zones to isolate sharp analyte peaks at their boundaries. Solvent system: methyl *t*-butyl ether–acetonitrile–water (4 : 1 : 5); retainer acids: TFA, acetic acid, propionic acid, and *n*-butyric acid, each $0.4 \mu\text{L mL}^{-1}$ in the organic stationary phase; eluter base: 0.1% ammonia in the aqueous mobile phase (pH 10.77); sample: DNP-L-aspartic acid, DNP-L-alanine and DNP-L-leucine each 1 mg; flow-rate: 3 mL min^{-1} ; revolution: 800 rpm; retention of the stationary phase = 81.0%.

creased by 100-fold from 1 to 100 mg, under otherwise identical conditions, the upper chromatogram shown in Figure 5 was obtained. Each component formed a highly concentrated rectangular peak associated with a specific pH as shown by the dotted line. The elimination of the three spacer acids (Figure 5, lower) resulted in fusion of these three peaks while preserving their original rectangular shapes as demonstrated by well-defined pH-zones and K_{std} values measured with a standard solvent system (chloroform–acetic acid–0.1 M HCl at a volume ratio of 2 : 2 : 1) as shown in the lower chromatogram.

This new modification of the HSCCC method produces characteristic pH-zones according to pK_a and hydrophobicity of analytes and for this reason it has been named ‘pH-zone-refining CCC’. It shares many features with displacement chromatography and provides several advantages over the conventional HSCCC technique such as increased sample loading capacity, high concentration of fractions, concentration and detection of minor components, and detection and precise localization of rectangular major peaks by monitoring the effluent pH even though the analytes have no chromophore. Of course, unlike standard HSCCC, it depends on the ability of an analytes to exist in two different forms, one hydrophobic and one hydrophilic.

Mechanism of pH-zone-refining CCC

Model Experiment

The mechanism of pH-zone-refining CCC may be demonstrated by the following model experiments. Figure 6 shows preparation of solvent phases to initiate the experiment for separating acidic analytes. About equal volumes of ether and water are equilibrated in a separatory funnel and the two phases separated. A retainer acid such as TFA is added to the upper organic phase (shaded) while an eluter base such as ammonia is added to the lower aqueous phase. In each experiment the column is first entirely filled with the stationary phase. This is followed by injection of sample solution containing three acidic

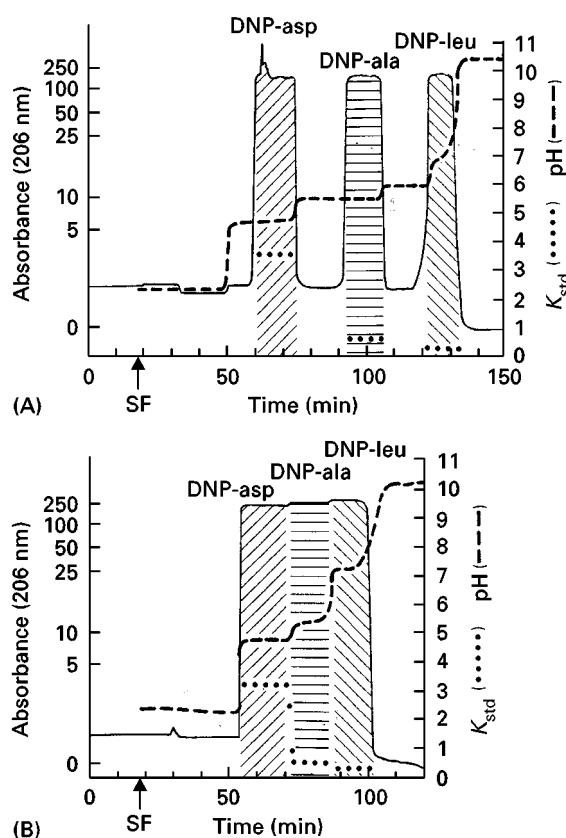

Figure 5 pH-zone-refining CCC of DNP-amino acids with (A) and without (B) spacer acid in the stationary phase. (A) Rectangular peaks of three DNP-amino acids were widely separated from each other by the spacer acids (acetic acid, propionic acid and *n*-butyric acid). (B) Elimination of the spacer acids resulted in fusion of the rectangular peaks with minimum overlapping as demonstrated by associated pH values and partition coefficient values (K_{std}). Experimental conditions are identical to those in Figure 4, except that the sample size was increased to 100 mg for each component. The K_{std} values were obtained by partitioning an aliquot of each fraction to the standard solvent system composed of chloroform–acetic acid–0.1 M HCl (2 : 2 : 1) (SF = solvent front).

Figure 6 Model experiment for pH-zone-refining CCC for separation of carboxylic acids: preparation of solvent phases.

analytes. The mobile phase then is pumped into the column and the column rotated at a desired rate.

Figure 7 (upper diagram) illustrates the result of the experiment where a portion of the separation column shows the organic stationary phase (shaded) in the upper half and the aqueous mobile phase in the lower half. As described by its nonlinear isotherm, the retainer acid, TFA, forms a sharp boundary which moves through the column space occupied by the mobile phase at a rate considerably lower than that of the mobile phase. Three analytes, S_1 , S_2 , and S_3 , competitively form solute zones behind the sharp TFA border according to their pK_a and hydrophobicity. S_1 , with the lowest pK_a and hydrophobicity, is located immediately behind the TFA border, while S_3 with the highest pK_a and hydrophobicity is located at the end of the solute zones where it forms a sharp rear border.

As indicated by curved arrows, proton transfer takes place at each zone boundary governed by the difference in pH between the neighbouring zones. The loss of the solute from the mobile phase to the stationary phase at the zone front is compensated for by its return at the back of each zone, while ammonium ions in the aqueous phase serve as counterions for all species. After reaching equilibrium all three solute zones move at the same rate as that of the TFA border, while constantly maintaining their indi-

vidual widths and pH. Charged minor components present in each zone are efficiently eliminated either forward or backward according to their partition coefficients (pK_a and hydrophobicity) and eventually accumulate at the zone boundaries. Consequently, the three analytes elute as a train of rectangular peaks with sharp impurity peaks at their narrow boundaries as illustrated in the lower diagram of **Figure 7**.

A similar experiment can be performed by using the acidified organic phase as the mobile phase. In this displacement elution mode the sharp retainer border is formed behind the solute zones, and the order of the elution for three solutes are reversed, forming a downward staircase pattern of the pH curve.

Distribution Equilibrium of Solute and Retainer Acid Within the Separation Column

Figure 8 shows the simplified distribution equilibrium of TFA (CF_3COOH) and solute S ($RCOOH$) between the stationary organic phase and the flowing aqueous phase on the assumption that the concentration of ionized components in the organic phase is negligible. The pH of the mobile phase in the solute zone (zone S) on the left-hand side of the sharp TFA border is given from the following three equations:

$$K_{D-s} = [RCOOH_{org}]/[RCOOH_{aq}] \quad [1]$$

$$K_s = [RCOOH_{org}]/([RCOOH_{aq}] + [RCOO^-_{aq}]) \quad [2]$$

$$K_{a-s} = [RCOO^-_{aq}] [H^+_{aq}]/[RCOOH_{aq}] \quad [3]$$

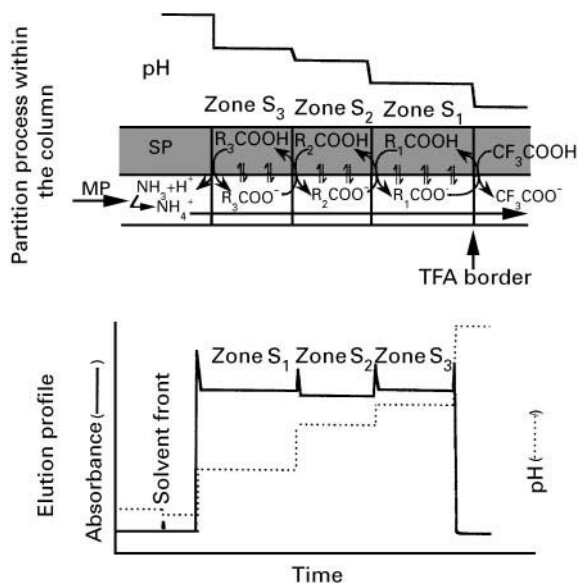

Figure 7 Model experiment for pH-zone-refining CCC for separation of carboxylic acids: partition process within the column and elution profile.

Figure 8 Distribution equilibrium of various species on both sides of the sharp TFA retainer border in the separation column.

where K_{D-s} is the partition ratio of solute S (RCOOH) and K_{D-s} , the dissociation constant of the solute. These equations reduce to

$$\text{pH}_{z-s} = \text{p}K_a + \log \left\{ (K_{D-s}/K_s) - 1 \right\} \quad [4]$$

where pH_{z-s} is pH of the mobile phase in the solute zone. As shown in the above equation, the pH of the solute zone is determined by the $\text{p}K_a$ and hydrophobicity (K_{D-s}) of the solute as well as its partition coefficient (K_s).

Figure 9 shows the relationship between the pH of the mobile phase and the solute partition coefficient (K) within the column (left) and the profile of pH-zones eluted (right). These curves may be drawn from eqn [4] by inserting the actual values of K_{D-s} and $\text{p}K_a$ for the solutes. If these parameters are not available, each curve can be obtained experimentally by dissolv-

ing various amounts of solute in the solvent system (containing the eluter base but no retainer acid), and measuring the pH of the lower aqueous phase and the solute concentration in both phases. Then the diagram can be constructed by plotting the pH on the ordinate against K (the solute concentration in the upper organic phase divided by that of the lower aqueous phase) on the abscissa. As described by the non-linear isotherm, K increases with increasing amounts of solute which causes a decrease in pH. In Figure 9 (left) five pH curves are arranged from the top to bottom in the order of decreasing $\text{p}K_a$ of the solutes where the lowest curve represents that of the retainer acid with the lowest $\text{p}K_a$. The vertical line drawn through the critical K value, called the operating line, intersects each pH curve and determines the pH level in the corresponding solute zone eluted as shown in the diagram on the right.

Figure 9 Relationship between pH/ K curves and eluted pH-zones.

This pH vs K diagram is useful for predicting the experimental results including the order of solute elution, the pH level of each solute zone, and the feasibility of the separation. A good separation is expected from a set of pH curves which show well-separated curves with even distributions.

pH-zone-refining CCC vs Displacement Chromatography on a Solid Support

As described earlier pH-zone-refining CCC closely resembles displacement chromatography in many aspects, including formation of highly concentrated rectangular peaks, concentration of minor components at the boundaries of the major peaks and isotachic movement (moving at the same rate) of all solute zones. However, an important difference between the two is that in pH-zone-refining CCC a retainer or an eluter agent transfers the analytes from the stationary phase to the mobile phase by either protonation or deprotonation, which changes the partition coefficient of the analytes. In displacement chromatography on a solid support, the displacer displaces analytes by transferring it from the solid support to the mobile phase. Another important difference between the two methods is the concentration of the analyte in the mobile phase. In displacement chromatography, concentration of the analyte is determined by its adsorption onto the solid support. Consequently, the earlier eluting analyte shows a lower concentration than the later eluting analytes. In pH-zone-refining CCC, on the other hand, the analyte concentration is mainly determined by the molar concentration of the counterion in the aqueous phase, and therefore all monovalent analytes are eluted at similar molar concentrations in the aqueous mobile phase. Similarities and differences between the two techniques are summarized in Table 1.

Application of pH-zone-refining CCC

The applications of pH-zone-refining CCC are presented here under two subheadings: standard and affinity separations. pH-zone-refining CCC separation is usually performed with a retainer agent in the stationary phase and an eluter agent in the mobile phase. However, the separation of certain groups of compounds requires an additional agent, a ligand, in the stationary phase. Such groups include enantiomers, highly polar analytes such as catecholamines and sulfonated dyes, and zwitterions such as amino acids and peptides. Samples, solvent systems and essential ingredients such as retainers, eluters and ligands used in various applications for the standard and affinity pH-zone-refining CCC techniques are summarized in Tables 2 and 3, respectively.

The following examples of pH-zone-refining-CCC separations have been performed using a HSCCC centrifuge equipped with a semi-analytical multilayer coil of 1.6 mm internal diameter having a total capacity of about 320 mL. In the conventional HSCCC technique the sample loading capacity of this column is limited to a few hundred milligrams.

Standard Separations

Amino acid derivatives Three chromatograms of DNP-amino acids shown in Figure 10 demonstrate the capability of pH-zone-refining CCC. All separations were performed with the same solvent system composed of methyl *t*-butyl ether–acetonitrile–water at a volume ratio of 4 : 1 : 5 where a 200 μ L quantity of TFA (retainer acid) was added to the sample solution, and 0.1% v/v aqueous ammonia (28%) (eluter base) to the aqueous mobile phase to raise the pH to 10.5.

The top chromatogram was obtained from 6 mg of the sample mixture consisting of six different

Table 1 Comparison between pH-zone-refining CCC and displacement chromatography

	pH-zone-refining CCC		Displacement chromatography using solid support
	Standard mode	Displacement mode	
Key reagents	Retainer	Eluter	Displacer
Solute transfer (phase)	Mobile \rightarrow Stationary	Stationary \rightarrow Mobile	Stationary \rightarrow Mobile
Action location	Front of solute bands	Back of solute bands	Back of solute bands
Formation of solute bands	A train of individual solute bands with minimum overlapping		
Travelling rate of solute bands	All solute bands move together at the same rate as that of the key reagent.		
K^* in solute bands	Same as and determined by that of the key reagent for all solutes		
Impurities	Concentrated at the boundaries of the solute bands		
Peak profile	A train of rectangular peaks associated with sharp impurity peaks at their boundaries		
Solute concentration in mobile phase is determined by	Concentration of counterions in aqueous phase		Solute affinity to stationary phase
Elution order is determined by	Solute pK_a and hydrophobicity		Solute affinity to stationary phase

* K is the partition coefficient expressed by solute concentration in the stationary phase divided by that in the mobile phase.

DNP-amino acids. All components were eluted together as a sharp single peak without any visible evidence of separation. When the sample size was increased 100 times, i.e. from 6 to 600 mg, the ultra-violet (UV) trace at 206 nm produced a highly concentrated rectangular peak which was divided into six flat pH-zones (dotted line) as shown in the middle chromatogram. The partition coefficient of fractions measured with a standard solvent system composed of chloroform–acetic acid–0.1 M HCl revealed that each pH-zone corresponds to one species as indicated in the chromatogram. The bottom chromatogram illustrates the separation of 500 mg each of DNP-glutamic acid and DNP-valine under similar conditions. Each component formed a long plateau associated with its specific pH where the length of each

plateau increased in proportion to the applied sample size. A sharp transition between the two plateaus indicates minimum overlap between the two peaks. A gradual decline of pH curves in both pH-zones was apparently caused by a steady increase of the travelling rate of the retainer acid border and the following solute zones through the column, since the retainer acid was added exclusively to the sample solution.

pH-Zone-refining CCC can be equally well applied to the separation of basic compounds using a retainer base such as triethylamine and an eluter acid such as hydrochloric acid. This was first demonstrated by the separation of amino acid benzyl esters. **Figure 11** shows a chromatogram of a set of amino acid benzyl esters using a two-phase solvent system composed of methyl *t*-butyl ether and water where triethylamine

*DNB: dinitrobenzoyl.

†MBE: methyl *t*-butyl ether; AcN: acetonitrile; BuOH: *n*-butanol.‡TFA: trifluoroacetic acid; NH₄OAc: ammonium acetate; TEA: triethylamine; DPA: N-dodecanoyl-L-proline-3,5-dimethylanilide; DEHPA: di-(2-ethylhexyl) phosphoric acid; TDA: tridodecylamine; SP: organic stationary phase; MP: aqueous mobile phase.

(10 mM) was added to the organic stationary phase and hydrochloric acid (10 mM) to the aqueous mobile phase. Seven components were well resolved in 3 h.

The preparative separations of three amino acid benzyl esters are shown in **Figure 12** where three sample sizes of 0.6 g (A), 3 g (B) and 6 g (C) were separated with the same solvent system composed of methyl *t*-butyl ether–water, where 5 mM triethylamine was added to the organic stationary phase and 20 mM HCl to the aqueous mobile phase. Comparison of these three chromatograms clearly shows that the increase of the sample size results in a proportional increase of the peak width whereas the width of the mixing zones remains the same as indicated by the sharp transition of the standard *K* values between the peaks (*x*-line). This again demonstrates the great potential of the technique for preparative-scale separations.

Peptide derivatives Peptides can be fractionated easily by pH-zone-refining CCC in a manner similar to that for the amino acid derivatives described above, if either amino or carboxylic terminal is blocked. **Figure 13** shows separations of a set of Z or CBZ (carbobenzoyloxy)-dipeptides by pH-zone-refining CCC using a two-phase solvent system composed of methyl *t*-butyl ether–acetonitrile–water (2 : 2 : 3, v/v) with 16 mM TFA in the organic stationary phase and 5.5 mM ammonia in the aqueous mobile phase. Eight components, each 100 mg, were well resolved within 4 h. A gram-quantity separation of three components, Z-gly-gly, Z-gly-ala and Z-gly-leu, was also successfully performed with a similar solvent system.

Alkaloids Many alkaloids may be effectively separated by pH-zone-refining CCC using triethylamine in the organic phase and HCl in the aqueous phase. **Figure 14** shows chromatograms of alkaloids from a crude amaryllis extract. The separation was performed with a two-phase solvent system composed of methyl *t*-butyl ether–water. The upper chromatogram was obtained by eluting with an aqueous phase and the lower chromatogram by eluting with an organic phase (displacement mode). In both elution modes three components were well resolved. The sample size was 3 g in each separation. Elution with the organic phase yields a free base in an organic solvent which is easily evaporated. For unstable alkaloids, aqueous phase elution may be preferred because the sample is collected in the salt form that is often more stable.

Figure 15 shows a chromatogram obtained from a crude extract of *Vinca minor* by the displacement mode of pH-zone-refining CCC. Two major components, vincine and vincamine, were separated and each eluted as a free base in about 2 h. Irregularity of the pH curve was caused by instability of the pH reading obtained from the organic mobile phase.

Miscellaneous separations The method can be very useful for purification of structural isomers from a crude synthetic reaction. **Figure 16** shows a separation of 2- and 6-nitro-4-chloro-3-methoxybenzoic acids by pH-zone-refining CCC. An 11.7 g amount of the crude reaction mixture was resolved into two peaks in 3 h, the 6-nitro isomer (3.1 g) and 2-nitro isomer (5.9 g) with a mixing zone (0.7 g). One of the

pH-zone refining CCC of DNP amino acids

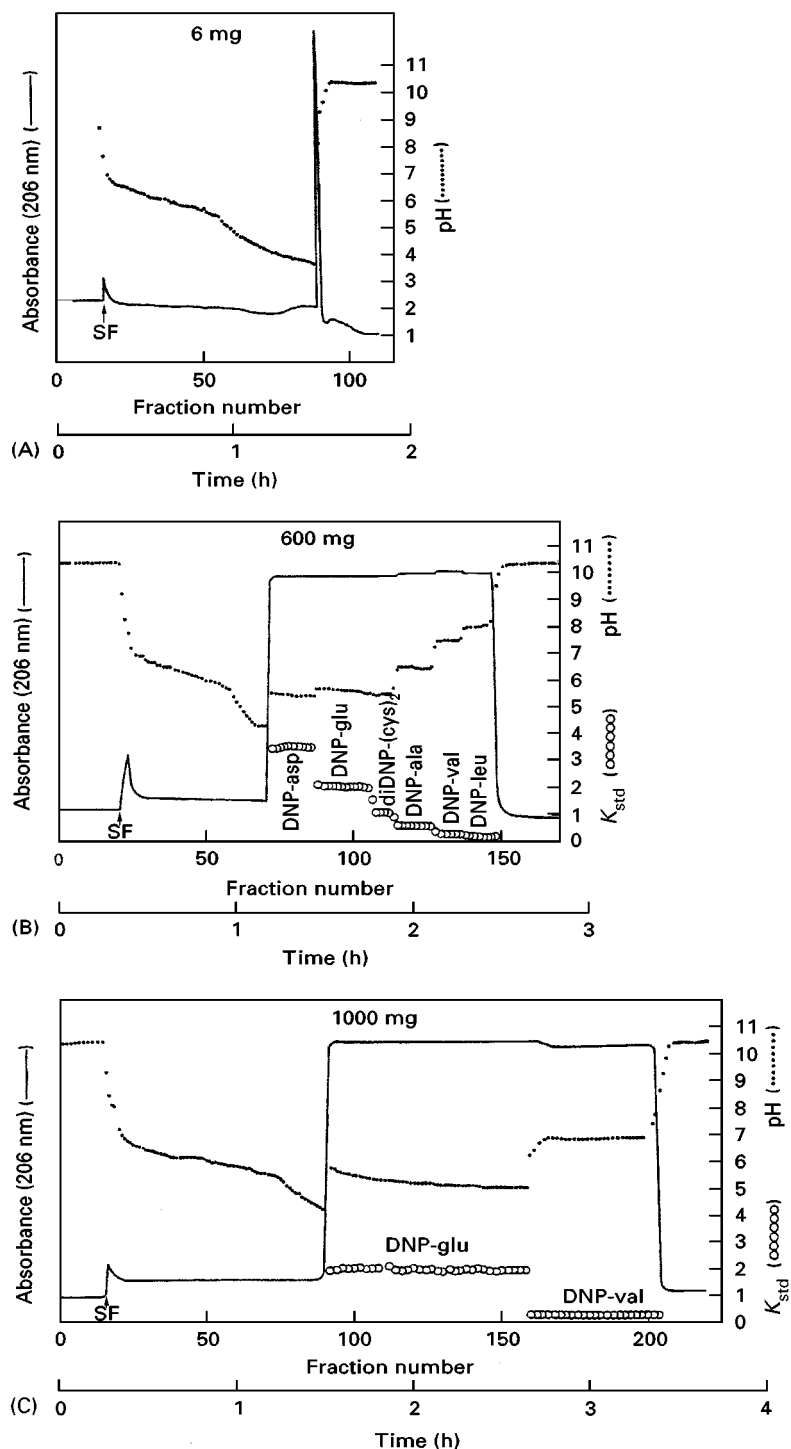

Figure 10 Chromatogram of DNP-amino acids. Top: separation of a small amount (6 mg) of six different DNP-amino acids. Middle: separation of large amounts (600 mg) of the above six DNP-amino acids. Bottom: separation of large quantities of DNP-L-glutamic acid and DNP-L-valine (500 mg of each). SF = solvent front. Solvent system: methyl *t*-butyl ether–acetonitrile–water (4 : 1 : 5) where 0.1% aqueous NH_3 (approximately 14 mM) was added to the aqueous mobile phase (pH 10.5) and 200 μL TFA was added to the sample solution; flow-rate: 3 mL min^{-1} ; detection: 206 nm; revolution: 800 rpm.

Figure 11 Separation of seven amino acid benzyl esters by pH-zone-refining CCC. Solvent system: methyl *t*-butyl ether/water, 10 mM triethylamine in upper organic stationary phase and 10 mM hydrochloric acid in lower aqueous phase; sample: a mixture of seven amino acid benzyl esters as indicated in the chromatogram, 100 mg each dissolved in 20 mL solvent; flow-rate: 3 mL min⁻¹; detection: 206 nm; revolution: 800 rpm; retention of stationary phase: 71.2%.

advantages of pH-zone-refining CCC is that compounds with no chromophore can be conveniently monitored by pH alone: the fractions of major components are located in their flat pH-zones and those of minor components at their boundaries, since in accord with eqn [4] they are unlikely to have identical or compensating pK_a and hydrophobicity. This potential is demonstrated in the separation of the stereoisomers of 1-methyl-4-methoxymethylcyclohexane carboxylic acid, using octanoic acid as a spacer. As shown in Figure 17, the two isomers were eluted after the octanoic acid each forming a pH-zone with a relatively narrow mixing zone. The collected fractions were analysed by gas chromatography-mass spectrometry (GC-MS) of their esters as indicated in the upper part of the figure.

The pH-zone-refining CCC separations of hydroxyxanthene dyes and sulfonated dyes are described under separation of dyes (high-speed countercurrent chromatography).

Affinity Separations

Enantiomers In CCC, which uses no solid support in the column, the chiral selector is simply dissolved in the liquid stationary phase to carry out the separation by either conventional or pH-zone-refining CCC.

The chromatogram in Figure 18 was obtained from 2 g of a DNB-leucine racemate using an affinity

ligand, *N*-dodecanoyl-L-proline-3,5-dimethylanilide (DPA) in the stationary phase. The racemic mixture was resolved in highly concentrated rectangular peaks with minimum overlap. The fractions were analysed by analytical CCC as indicated in the diagram, using the same chiral selector, and also with CD and optical rotation instruments. This technique should be very useful in the pharmaceutical industry where an ever-increasing number of drugs are now required to be produced in chirally pure forms.

Catecholamines Catecholamines containing two or more hydroxyl groups strongly favour partition into the aqueous phase even in a polar butanol two-phase solvent system. However, the use of a ligand such as di(2-ethylhexyl)phosphoric acid (DEHPA) in the organic stationary phase radically improves their partition behaviour so that pH-zone-refining CCC of a mixture of 100 mg each of four polar catecholamines and two related compounds using the above ligand in the stationary phase can be well resolved in 3 h.

Peptides For pH-zone-refining CCC of free peptides a series of experiments was performed using DEHPA as a ligand in the stationary phase. A set of three dipeptides with a broad range in hydrophobicity was separated with a solvent system composed of methyl *t*-butyl ether, acetonitrile and water at a volume ratio

Figure 12 Separation of three amino acid benzyl esters by pH-zone-refining CCC. Solvent system: methyl *t*-butyl ether/water, 5 mM triethylamine in organic stationary phase and 20 mM hydrochloric acid in aqueous mobile phase; sample: gly(OBzl)·Tos, leu(OBzl)·Tos and glu(OBzl)·Tos, each 0.2 g (A), 1 g (B) and 2 g (C); flow-rate: 3 mL min⁻¹; detection 206 nm; revolution: 800 rpm; retention of stationary phase: 76.5% (A), 63.3% (B) and 77.8% (C).

of 4 : 1 : 5 where triethylamine and various amount of the ligand were added to the organic stationary phase and HCl to the aqueous mobile phase. The

results are shown in the left three chromatograms in **Figure 19**. At a 10% ligand concentration, the second and third peaks were fused together while the polar

Figure 13 Separation of eight CBZ(Z)-dipeptides by pH-zone-refining CCC. Solvent system: methyl *t*-butyl ether–acetonitrile–water (2 : 2 : 3, v/v), 16 mM TFA in organic stationary phase (pH 1.83) and 5.5 mM NH_3 in aqueous mobile phase (pH 10.62); sample: eight CBZ-dipeptides as indicated in the chromatogram, each 100 mg dissolved in 50 mL solvent (25 mL each phase); flow-rate: 3.3 mL min^{-1} in the head-to-tail elution mode; detection: 206 nm; revolution: 800 rpm (first 66 mL eluted at 600 rpm to prevent the carryover of the stationary phase); stationary phase retention: 65.1%.

tyrosyl-glycine peak was eluted earlier. Increasing the ligand concentration to 20–30% resulted in fusion of the first and second peaks while the hydrophobic tyrosyl-leucine peak was isolated and eluted much

later. Increasing the polarity of the solvent system by modifying the phase composition improved the sharpness of the fused first and second peaks as shown in the right-hand chromatogram. The results

Figure 14 Chromatograms of crude alkaloid extract of solvent *Crinum moorei* obtained by standard mode (A) and displacement mode (B) of pH-zone-refining CCC. Solvent system: methyl *t*-butyl ether/water; stationary phase: (A) organic phase (5 mM triethylamine) and (B) aqueous phase (10 mM HCl); mobile phase: (A) aqueous phase (5 mM HCl) and (B) organic phase (10 mM triethylamine); flow-rate: 3.3 mL min^{-1} ; sample: crude alkaloid extract of *Crinum moorei*, 3 g dissolved in 30 mL of each phase; detection: 206 nm; revolution: (A) 800 rpm (600 rpm until 66 mL of mobile phase was eluted) and (B) 600 rpm throughout.

Figure 15 Separation of alkaloids from *Vinca minor* by pH-zone-refining CCC using displacement mode. Solvent system: methyl *t*-butyl ether/water, 5 mM triethylamine in organic mobile phase and 5 mM HCl in aqueous stationary phase; flow-rate: 3.3 mL min^{-1} in tail-to-head elution mode; sample: crude alkaloid extract of *Vinca minor*, 300 mg dissolved in 30 mL of solvent system (equal volumes of each phase); detection: 206 nm; revolution: 800 rpm; retention of stationary phase: 90.4%.

Figure 16 Separation of crude reaction mixture of 2- and 6-nitro-4-chloro-3-methoxybenzoic acids by pH-zone-refining CCC. Solvent system: methyl *t*-butyl ether-acetonitrile-water (4 : 1 : 5), TFA was added to the upper organic stationary phase at 0.3% (12 mM, pH 2.2) and ammonia 0.8% (100 mM, pH 10.6) to the lower aqueous mobile phase; sample: crude reaction mixture (11.7 g) of two isomers indicated in the figure; flow-rate: 3 mL min^{-1} ; detection: 280 nm; revolution: 800 rpm.

Figure 17 Separation of *trans*- and *cis*-stereoisomers of 1-methyl-4-methoxymethylcyclohexanecarboxylic acid by pH-zone-refining CCC using octanoic acid as a spacer. Solvent system: methyl *t*-butyl ether–acetonitrile–water (4 : 1 : 5), 0.32% TFA in organic stationary phase (pH 1.74), and 0.8% aqueous ammonia in aqueous mobile phase (pH 11.2); flow-rate: 3 mL min⁻¹ in head-to-tail elution mode; sample: crude nitration product of 3-acetamido-4-chlorobenzoic acid (15 g) dissolved in 100 mL in equal volumes of each phase and the pH adjusted to 8.7 with aqueous ammonia; detection: 206 nm; revolution: 800 rpm (600 rpm until 66 mL of mobile phase was eluted). In analysis of fractions by GC/MS as indicated above the main chromatogram, the acids were converted to their methylesters for chromatographic purposes.

of these preliminary studies indicated that both ligand concentration and solvent composition should be adjusted according the hydrophobicity of the peptides. Under optimized conditions, pH-zone-refining CCC of dipeptides was successful. As shown in **Figure 20**, both polar and non-polar groups of dipeptides, each consisting of two isomeric pairs, were well resolved in 3–4 h.

Five grams of bacitracin complex consisting of multiple components were subjected to pH-zone-refining CCC under optimized conditions similar to those applied to the hydrophobic dipeptides (**Figure 21**). The UV trace at 280 nm showed multiple peaks while the pH-curve yielded flat zones at around pH 2. As indicated by HPLC analysis, two major components, bacitracins A and F, were isolated.

Figure 18 Chiral separation of (±)-DNB-leucine by pH-zone-refining CCC using DPA as a ligand. CCC conditions: solvent system: methyl *t*-butyl ether/water, TFA (40 mM) + ligand DPA (40 mM) in organic stationary phase and ammonia (20 mM) in aqueous mobile phase; sample: (±)-DNB-leucine 2 g; flow-rate: 3 mL min⁻¹ in head-to-tail elution mode; detection: 206 nm; revolution: 800 rpm. Analytical CCC was carried out with the same column using the conventional HSCCC technique under the following conditions: solvent system: hexane-ethyl acetate-methanol-10 mM HCl (8 : 2 : 5 : 5), organic stationary phase containing DPA (20 mM); flow-rate: 3 mL min⁻¹ in head-to-tail elution mode; detection: 254 nm; revolution: 800 rpm.

Detailed technical guidance for performing pH-zone-refining CCC including the choice of two-phase solvent systems, the preparation of sample solution, separation procedures, and so on has been given in the literature.

Advantages of pH-zone-refining CCC

The applications described here demonstrate the advantages of the pH-zone-refining CCC method over the conventional HSCCC technique as well as over many other commonly employed chromatographic procedures. These include:

1. Sample loading capacity is increased over 10 times for a given column.
2. Fractions are highly concentrated.
3. Increase in sample size produces a higher percentage of pure fractions.
4. Minor components are concentrated and detected at the boundaries of the major peaks.
5. Sample with no chromophore can be effectively monitored by pH.

On the other hand, pH-zone-refining CCC has the following limitations: the analytes must be ionizable and, if they have similar hydrophobicities, their pK_a s should differ by 0.2 or greater. In addition, the sample size should be at least 0.1 mmol and preferably more, for each species, so it is not applicable to trace quantities. This limitation could be overcome if the column diameter were able to be sufficiently

Figure 19 Separation of 3 dipeptides by pH-zone-refining CCC using DEHPA in the stationary phase. Sample: three dipeptides indicated in the chromatogram, each 100 mg; flow-rate: 3 mL min^{-1} in head-to-tail elution mode; detection: 280 nm; revolution: 800 rpm.

Figure 20 Separation of dipeptides by pH-zone-refining CCC. Hydrophobic (right) and hydrophilic (left) groups of dipeptides each consisting of two isomeric pairs were separated under the optimized conditions. Solvent systems: hydrophobic group: methyl *t*-butyl ether–acetonitrile–water (4 : 1 : 5) 20 mM triethylamine and 10% DEHPA in organic stationary phase and 20 mM HCl in aqueous mobile phase, hydrophilic group: methyl *t*-butyl ether–*n*-butanol–acetonitrile–water (2 : 2 : 1 : 5) 20 mM triethylamine and 30% DEHPA in organic stationary phase and 20 mM HCl in aqueous mobile phase; flow-rate: 3 mL min^{-1} in head-to-tail elution mode; sample: dipeptides indicated in the chromatogram, total amount of 1 g for each group; detection: 280 nm; revolution: 800 rpm.

Figure 21 Preparative separation of bacitracin complex by pH-zone-refining CCC. Solvent system: methyl *t*-butyl ether-acetonitrile-water (4 : 1 : 5), 40 mM triethylamine and 10% DEHPA in organic stationary phase, and 20 mM HCl in aqueous mobile phase; flow-rate: 3 mL min⁻¹; sample: 5 g of bacitracin dissolved in 40 mL of solvent (20 mL each phase); detection: 280 nm; revolution: 800 rpm.

reduced. Of course, the technique can be used to concentrate trace quantities by the pH-peak-focusing CCC mentioned earlier.

The above features of pH-zone-refining CCC suggest that the method possesses great potential for preparative-scale research separations. Because of its unique ability to handle large-scale separations, the

method should find particular application in many industrial processes.

Introduction

Thin-layer chromatography (TLC) represented a key development in aquatic sciences because it enabled the routine separation and quantitation of algal chlorophylls, carotenoids and their breakdown products (Table 1 and Figure 1) to be obtained. These pigments can be used as markers for algal taxa, processes such as grazing or cell senescence and water masses. However, TLC methods are not easy to automate, are difficult to use in field situations and have gradually given way to liquid chromatography (LC) methods.

High performance LC (HPLC) analysis of pigments has been developed over the last 20 years. Both normal-phase (NP) and reversed-phase (RP) techniques have been used, with preference for the RP mode due to the relatively low polarity of the analysed compounds. The NP mode is now mostly used for the separation of specific pigments (e.g. monovinyl from

divinyl chlorophylls) while RP-HPLC is preferred when a complete separation of all major chlorophylls and carotenoids is required. The analysis of phycobiliproteins, the other major group of algal pigments, is not yet done by chromatographic separation on a routine basis.

Within the various RP-HPLC methods, gradient elution has generally been preferred over isocratic for full pigment separation. Ion-pairing reagents, or phase buffering, have been included in a number of techniques to improve the resolution of the more polar pigments. Three groups of pigments present particular difficulties in their separation: the pigment pair lutein–zeaxanthin, the various members of the chlorophyll *c* group and the monovinyl and divinyl forms of chlorophyll *a* and *b*. Improved separation of zeaxanthin and lutein has been achieved using a nonend-capped C_{18} column (see below) and a combination of acetonitrile, methanol and ethyl acetate as mobile phase. Resolution of chlorophyll c_3 from the other compounds in the chlorophyll *c* group has been obtained by including an ammonium acetate buffer in the initial methanol mobile phase. Separation of all three forms of chlorophyll *c* has been achieved on a polyethylene column using aqueous acetone as mobile phase, as well as by using a very high ion strength solvent in combination with a high carbon loaded

Table 1 Major algal chlorophyll and carotenoid pigments

Name	Molecular formula	Occurrence
<i>Chlorophylls</i>		
Chlorophyll <i>a</i> (monovinyl)	C ₅₅ H ₇₂ N ₄ O ₅ Mg	All photosynthetic algae and higher plants
Divinyl chlorophyll <i>a</i>	C ₅₅ H ₇₀ N ₄ O ₅ Mg	Some prochlorophytes
Chlorophyll <i>b</i> (monovinyl)	C ₅₅ H ₇₀ N ₄ O ₆ Mg	Green algae, symbiotic prochlorophytes and higher plants
Divinyl chlorophyll <i>b</i>	C ₅₅ H ₆₈ N ₄ O ₆ Mg	Some prochlorophytes
Chlorophyll <i>c</i> ₁	C ₃₅ H ₃₀ N ₄ O ₅ Mg	Chromophyte algae, brown seaweeds
Chlorophyll <i>c</i> ₂	C ₃₅ H ₂₈ N ₄ O ₅ Mg	Chromophyte algae, brown seaweeds
Chlorophyll <i>c</i> ₃	C ₃₆ H ₂₈ N ₄ O ₇ Mg	Some prymnesiophytes, chrysophytes and diatoms
Mg-3,8-divinyl phytylporphyrin-132-methyl carboxylate	C ₃₅ H ₃₀ N ₄ O ₅ Mg	Some prasinophytes
<i>Chlorophyll degradation products</i>		
Chlorophyllide <i>a</i>	C ₃₅ H ₃₄ N ₄ O ₅ Mg	Senescent algae
Pheophytin <i>a</i>	C ₅₅ H ₇₄ N ₄ O ₅	Algal and plant detritus (also small concentration in photosynthetic reaction centres)
Pheophorbide <i>a</i> + same types of degradation products for the other chlorophylls	C ₃₅ H ₃₆ N ₄ O ₅	Zooplankton faecal pellets and marine detritus
<i>Carotenoids</i>		
Alloxanthin	C ₄₀ H ₅₂ O ₂	Cryptophytes
Astaxanthin	C ₄₀ H ₅₂ O ₄	Some green algae + marine animals
19'-Butanoyloxyfucoxanthin	C ₄₆ H ₆₄ O ₈	Pelagophytes, some prymnesiophytes and dinoflagellates
β,γ-Carotene	C ₄₀ H ₅₆	Minor pigment in green and red algae and in cryptophytes
β,β-Carotene	C ₄₀ H ₅₆	Green and chromophyte algae and higher plants
Crococanthin	C ₄₀ H ₅₄ O	Cryptophytes
Diadinoxanthin	C ₄₀ H ₅₄ O ₃	Diatoms, prymnesiophytes, some chrysophytes and dinoflagellates
Echinenone	C ₄₀ H ₅₄ O	Cyanobacteria + some green algae
Fucoxanthin	C ₄₂ H ₅₈ O ₆	Diatoms, prymnesiophytes, brown seaweeds, some dinoflagellates
19'-Hexanoyloxyfucoxanthin	C ₄₈ H ₆₈ O ₈	Many prymnesiophytes, some dinoflagellates
Lutein	C ₄₀ H ₅₆ O ₂	Green algae, red seaweeds, higher plants
Neoxanthin	C ₄₀ H ₅₆ O ₄	Brown seaweeds, chrysophytes, green algae, higher plants
Peridinin	C ₃₉ H ₅₀ O ₇	Photosynthetic dinoflagellates
Prasinocanthin	C ₄₀ H ₅₆ O ₄	Some prasinophytes
Siphonein	C ₅₂ H ₇₈ O ₅	Green algae and siphonous green seaweeds
Vaucheriaxanthin (ester)	C ₄₀ H ₅₆ O ₅	Xanthophytes and eustigmatophytes
Violaxanthin	C ₄₀ H ₅₆ O ₄	Green algae, brown seaweeds and higher plants
Zeaxanthin	C ₄₀ H ₅₆ O ₂	Cyanobacteria, green algae, prochlorophytes, most chrysophytes and raphidophytes

fully end-capped C₁₈ column. The resolution of mono- from divinyl chlorophyll *a* and *b* can be obtained on a C₈ column or by varying the temperature of a polymeric C₁₈ column (see below).

The most complete, up-to-date information about the analysis of pigments, particularly for the use of aquatic scientists, can be found in a recent Scientific Committee on Oceanic Research (SCOR) UNESCO monograph edited by Jeffrey *et al.* This book covers sample collection, methods for pigment extraction and analysis, with emphasis on HPLC methods, comparisons with nonchromatographic methods, preparation of pigment standards and a key for identification of the various algal pigments.

Selection of Columns

Most methods attempting to separate the majority of pigments in a single step have used RP-HPLC with C₁₈ columns (Figure 2). Presently, the most popular C₁₈ columns for pigment analysis are the end-capped,

monomer-coated C₁₈ columns (Table 2), although these may not be the best for the separation of polar carotenoids. End-capping deactivates the remaining free silanol groups after the monomeric coverage. Columns from different companies differ in their carbon load (amount of bound C₁₈) and the type and extent of end-capping.

The separation of monovinyl from divinyl chlorophyll *a* and *b* was first achieved on NP silica columns, but these methods did not become very popular because of the reactivity of the stationary phase, the incompatibility of the extraction solvents with the technique and the lack of resolution of the polar pigments. These were replaced by C₈ columns, which can separate mono- from divinyl chlorophyll *a* and *b* but do not resolve all the chlorophyll *c* compounds (Figure 3).

The latest improvement in this field has been the development of columns which have multiple levels of C₁₈ bound to the silica (often called polymeric octadecylsilica columns). These allow the most

Figure 1 Chemical structures of major algal chlorophylls and carotenoids.

Figure 1 *Continued*

complete separation of chlorophylls and carotenoids but these coatings are more sensitive to temperature than monomeric columns, and hence the columns need to be thermostated. The work on marine pigments conducted in the laboratory of Zapata and Garrido has been instrumental in these developments

(Figure 4). Recently, research scientists in the field of food science have developed a polymeric triacontyl (C_{30}) column which provides adequate retention of polar carotenoids (e.g. good separation of lutein and zeaxanthin) as well as much improved separation of the nonpolar carotenes (Figure 5).

Figure 2 Analysis of pigments from ice algae from the Arctic (Roy, unpublished). Column 5 μ m. Spherisorb ODS-2 (C_{18}). Separation conditions: 50 : 50 of (85% methanol–15% ammonium acetate 0.5 mol L⁻¹) : (90% acetonitrile–10% water) to 30 : 70 of (90% acetonitrile–10% water) : ethyl acetate over 33 min; 0.8 mL min⁻¹. Temperature 27°C.

Table 2 Selection of columns for HPLC pigment analysis

Type of column	Carbon load	End-capping	Dimensions (mm)	Particle size (μm)	Type of analysis
<i>Reversed-phase (monomeric)</i>					
Spherisorb ODS-2 (C_{18})	12%	Yes	250 \times 4.6	5	Algal pigments
Ultrasphere C_{18}	12%	Yes	250 \times 4.6	5	Plant pigments
Zorbax ODS	20%	No	250 \times 4.6	5	Lutein/zeaxanthin
RSil C_{18}	16%	Yes	150 \times 4.6	5	Chlorophyll c_1 , c_2 , c_3
Hypersil MOS-2 (C_8)	6–7%	Yes	100 \times 4.6	3	MV and DV chlorophyll and lutein/zeaxanthin
<i>Reversed-phase (polymeric)</i>

elution mode. Initial conditions often include 80–90% methanol buffered with ammonium acetate, followed by 90% acetonitrile. Ethyl acetate or acetone is commonly used as the third solvent to elute the less polar pigments such as the pheophytins. The newer methods use the same solvents, except that an organic modifier is added to the methanol/acetonitrile eluent. Various five-carbon amino compounds have been tested as ion pair reagents, with aqueous pyridine showing the best results with the Vydac 201 TP column. Again, temperature control is essential when using these columns.

Detection

Detection of compounds eluting from HPLC columns is normally done by recording the absorbance (chlorophylls and carotenoids) or the fluorescence (chlorophylls) of algal pigments. Three types of detectors are commonly used for absorbance: fixed wavelength, variable wavelength and full spectrum absorbance detector. The fixed wavelength models are the most sensitive, but the least informative of the three. Full spectrum instruments are now a general requirement of any HPLC set-up for pigment analysis. They

include photodiode array detectors and rapid scanning instruments. Both allow the full absorbance spectrum of each peak to be collected without stopping the flow, facilitating identification of peaks, to the detriment, however, of sensitivity. Instruments with a lamp that has high output in the visible range (e.g. tungsten) are preferred for pigment analysis because of their increased sensitivity.

Fluorescence detectors are either of the filter type, with a band pass excitation filter and a long pass emission filter, or dual monochromator instruments. The filter type is often sufficient for most uses, especially if used in conjunction with an absorbance detector. The use of fluorescence detection along with absorbance detection allows confirmation of the identity of chlorophyll-type compounds since only these fluoresce. Fluorescence detection is also often preferred for quantitative use because of its great sensitivity.

Standards

Few pigment standards were available commercially, until recently (Table 3). However, the high cost of these standards, and the unavailability of a number of them, has prompted researchers to prepare in-house standards, using well-defined algal cultures. Guidelines for the preparation of standards can be found in the specialized literature, and summarized in the recent SCOR UNESCO monograph on algal pigments in oceanography.

Applications

The analysis of photosynthetic pigments is instrumental in numerous studies of the photosynthetic system of bacteria, plants and algae. It is also used in the fields of agriculture and food chemistry, in studies of food processing, and in the use of natural food-colouring agents. In aquatic sciences, algal pigments are used as an index of algal biomass and as biomarkers of different taxonomic groups of algae, particularly when HPLC analysis is applied. This information can then serve in the monitoring of red tides (toxic algal blooms), in studies of aquatic food webs in relation to harvestable resources or in the study of water masses in oceanography. The recent development of satellite remote-sensing of the colour of the oceans, related to their pigment composition and concentration, allows a synoptic perspective previously unobtainable from ship studies. Present studies are developing algorithms that can estimate primary production over wide areas of the oceans from remotely sensed (e.g. sea-viewing wide field-of-view sensor (SeaWiFS)) chlorophyll data.

Future Developments

Future advances in the field of pigment chromatography can be expected from:

1. development of new RP-HPLC columns, particularly the polymeric ones, and associated testing of the effect of temperature on the separation of pigments with these columns. HPLC equipment will also need to be more closely temperature-controlled to meet this need
2. advances in the field of mass spectrometry, such as electron impact, field desorption and fast atom bombardment, that permit volatilization of small quantities of pigments, and the coupling of mass spectrometry with HPLC (LC-MS) or with supercritical fluid chromatography (SFC-MS). These new methods should be particularly useful in studies dealing with degraded or derived pigments, such as fossil pigments found in sediments or transformation of pigments in food, agricultural, physiological or ecological studies.

General Introduction

Colour and Pigments

The colours found in natural organisms are of two types: those which are due to structural effects, and those which result from the presence of pigments. The two types of colouring often occur together. Examples of structural colour are to be found in the scales of fish, the wings of butterflies and the hair of many animals, although structural colour is also to be found in the plant world. The apparent colour depends on the interplay of these effects. It is thus important to realize at the outset that only the colour due to the pigments can be extracted. However, even then the *in vivo* and *in vitro* colours can be vastly different, since the pigments themselves show different colours according to the environment in which they occur – whether in fat globules or aqueous complexes.

Importance

Colour is used by almost all organisms to communicate in one form or another, for example, the defensive colours of insects, the attractive colours of flowers and fruit. The way in which various organisms pro-

duce pigments is genetically determined, and thus related organisms have similar pigment patterns and biologists use pigments to classify organisms at all levels. The commercial value of agricultural and particularly horticultural products is often closely related to their colour.

Natural Pigment Structures

The number of main pigment groups is relatively small. While various pigment groups are of vastly different skeletal types, there is usually little variation of the skeleton within each group and in many cases the possible group of pigments involved can be arrived at based on the observed colour in nature. Thus, while the green colour of chlorophylls is immediately recognizable, the typical flavonoids provide pale yellow colours, and the anthocyanidins, a special group of flavonoid salts, are usually responsible for red-blue colours in plants. The deep yellow to orange red shades resulting from the presence of carotenoids are also readily identified. Variations within a particular group are usually due to two factors: the degree of oxidation and the presence of substituents.

Extraction Methods

The different types of pigment vary greatly in polarity and in their sensitivity to chemical reagents, and thus require different extraction methods. It is best to avoid the use of acids or bases unless necessary, and

as far as possible exposure to air or light. It should be noted that working rapidly and with normal care may sometimes give better results than working with time-consuming rigorous methods, at least at a qualitative level. Normally, a solvent is found that will extract the required pigment type while extracting as little as possible of the remaining components from the substrate. This means essentially that the solvent and pigment type should match as well as possible with respect to polarity. However, even such tailored methods can fail if unusual or unsuspected substituents are present and lead to the identification of artefacts as naturally occurring.

Clean-up and Pretreatment

Even when extracts or individual pigments appear to be pure, the undisclosed presence of colourless impurities should always be investigated. Such impurities are normally readily disclosed by spraying a trial chromatogram with a strong oxidizing agent. This often provides valuable information before final chromatography is undertaken, since the presence of such impurities greatly reduces the efficiency of the plates, in terms of both resolution and capacity. The most common clean-up treatment is the extraction of polar impurities from less polar extracts, or the reverse where waxes are removed either before or after the extraction process. It is important to ensure the removal of residual solvents after such clean-up procedures, or indeed after saponification or hydrolysis, as they will otherwise result in inferior separation. Residual solvents are a common source of problems in chromatography and, in particular, the presence of even minor traces of water (easily removed by azeotropic distillation) can often spoil the separation of hydrophobic pigments.

Chromatography Layers

Chromatography may be carried out on layers coated on plastic or aluminium foils, or glass plates. The type used depends to some extent on whether a quantitative analysis is required since the backing is critical for densitometric methods. Commercial pre-coated plates have the advantage of uniform quality and give more reproducible results than laboratory-coated plates. The procedures given below have all been carried out on commercial plates for this reason. However, it should be noted that only a few adsorbents are available and the plates are expensive if large numbers are required. In addition, some commercial plates contain compounds used in their manufacture which may be extracted if the plates are used preparatively. It is normally possible, with practice, to produce laboratory-made plates that give sim-

ilar results, and in this case there are almost unlimited possibilities for mixing different adsorbents. In the case of larger scale preparative work, it is often easier to work with less dense home-made layers, although care should be taken in handling them to avoid damaging the layer.

Quantification

Densitometry is readily applied to the measurement of pigments, provided the usual precautions are taken to choose suitable wavelength, and drying of the developed plate is carried out in a manner that avoids excessive decomposition. Since pigments are usually worked with on small scales, thin layers are well suited for their preparative or semipreparative separation.

Pigment Groups

The pigment groups treated in more detail below are the main photosynthetic pigments, carotenoids and chlorophylls, and the most widely distributed flavonoid classes, with a separate section for the anthocyanins. Finally, other pigment types are discussed briefly.

Carotenoids

The carotenoids are probably the most widely distributed group of pigments, occurring in all photosynthetic organisms, in most animals and in a wide variety of microorganisms. They normally occur in the free form or as fatty acid esters, although carotenoproteins are common in marine animals and glycosides are found in some microorganisms. They are usually yellow to red in colour, although carotenoproteins are able to provide a full range of colours.

The carotenoids are tetraterpenoids and may be thought of as being made up by a central conjugated chain carrying two end-groups. Some typical carotenoids are shown in **Figure 1**. The number of possible end-group skeletons is quite restricted and structural variation largely derives from the type and position of the functional groups which they contain. The compounds containing only carbon and hydrogen are often called carotenes to differentiate them from their oxygenated analogues, which are then designated as xanthophylls. While all of the compounds in **Figure 1** have 40 carbon atoms, carotenoids containing partial skeletons are known, as are compounds carrying extra isoprenoid units to give skeletons having 45 and 50 carbon atoms.

Extraction methods for carotenoids depend somewhat on the organism being examined. Tissues from higher plants and microorganisms, where carotenoids

are usually present in the free form or as esters, can usually be extracted by hydrocarbon-acetone mixtures. Problems may be encountered with some microorganisms where it is necessary to disrupt the cells before extraction, where compounds may be strongly bound to cell wall material or, less often, where more polar solvents are required to extract glycosidic carotenoids. Animal tissues can contain carotenoproteins and in such cases a choice must be made between extraction with acetone which will free the hopefully unchanged carotenoids from the protein or extraction with suitable buffers of the intact carotenoproteins from which the carotenoids can then be liberated.

The normal procedure for carotenoid analysis is to examine the initial extract to decide whether the compounds are present in the free form or as esters. The esters themselves are much less polar than the free xanthophylls and a check can be made by saponifying an aliquot of the extract. Given a positive result a saponification step can then be applied to the whole extract, although it should be noted that some few carotenoids may suffer changes, e.g. astaxanthin, the main pigment in salmonoids, is changed to the closely related astacene by base treatment. One advantage of saponification of plant extracts is that the chlorophylls, which will otherwise interfere with chromatography, are destroyed and can be easily

Figure 1 Structures of some typical carotenoids.

**Figure 1** *Continued.*

removed prior to analysis. The effects of saponification can readily be seen in **Figure 2**, which shows a chromatogram of a paprika extract before and after saponification. The unsaponified extract is dominated by the presence of esterified carotenoids, while the esters are totally absent after saponification.

The finished saponified extract should be applied to the plate in a volatile solvent, usually acetone or diethyl ether. While a large number of stationary

phases have been employed, the most reliable are silica gel for normal-phase and octadecylsilylsilica for reversed-phase work, and these suffice to separate the normal range of pigments. If only carotenes are to be analysed, laboratory-coated magnesium oxide plates can be employed. R_F values are given for some common carotenoids in **Table 1**, for both normal-phase and reversed-phase systems. These values show immediately that retention is affected by the number

Figure 2 Chromatography of paprika (*Capsicum annuum*). Silica gel 60 (0.25 mm, Merck, Art. 5721) 40% acetone–petroleum ether. (A) Before saponification; (B) after saponification. Identification of zones: 1, β -carotene; 2, capsanthin diesters; 3, capsorubin diesters, 4, zeaxanthin and other diol diesters; 5, capsanthin monoesters; 6, capsorubin monoesters; 7, capsanthin; 8, cryptoxanthin, 9, zeaxanthin; 10, violaxanthin; 11, capsorubin, 12, neoxanthin. Only main zones are shown: filled zones indicate red colour; other zones are yellow.

and nature of functional groups present. Hydroxyl functions have greater effects than carbonyls, which in turn have greater effects than ether groups. Longer chains are more retained than shorter ones in normal-

phase chromatography, while the opposite is true for reversed-phase systems. It should be noted that, while development on silica gel layers with 40% acetone–petroleum ether (40–60°C) gives a generally similar result to that obtained with 20% of *tert*-butanol or *tert*-pentanol, carbonyls have markedly more retention in the latter systems. This difference in behaviour can be utilized when separating complicated mixtures of closely related carotenoids. The choice as to whether to use normal or reversed-phase plates will depend on the compounds present.

Practical procedures All operations with carotenoids should be carried out in dim light, avoiding exposure to air and acids and at temperatures not exceeding 40°C. Carotenoid samples and extracts should be kept in the refrigerator as far as possible.

Extraction The material to be extracted is cut into suitable pieces (1 cm cubes) suspended in three volumes of acetone and subjected to maceration for 2–3 min in a laboratory mixer. The solvent is removed and retained, and the procedure repeated twice. At this stage, much of the water present in the original tissue has been extracted and it is often advantageous to carry out one or two further extractions with acetone–petroleum ether (40–60°C) in a 1 : 1 v/v ratio. Where very polar carotenoids are present, extraction with solvent mixture containing methanol may be required. When the residue is colourless, the extracts are pooled and taken to dryness under reduced pressure. The extract can then be tested for the presence of esters and, in their absence, applied to the thin layers as solutions in diethyl ether or acetone. Otherwise saponification should be performed.

Saponification The dried extract is dissolved in a small amount of diethyl ether or methanol to give a deeply coloured concentrated solution which is then diluted with several volumes of diethyl ether. Saponification is then ensured by adding an equal volume of 10% methanolic sodium hydroxide, replacing the air in the flask with nitrogen, closing firmly, and after brief shaking allowing the mixture to stand at room temperature for 6 h in the dark. After this time the saponification mixture is diluted to three times its volume with 5% aqueous sodium chloride. The carotenoids are then extracted with similar volumes of diethyl ether until the diethyl ether extract is no longer coloured. The combined diethyl ether extracts are then pooled and washed to neutrality with successive portions (normally at least three) of 5% aqueous sodium chloride, before a final wash with

water. The washed extract is taken to dryness under reduced pressure and dissolved in either acetone or diethyl ether for analysis.

Chromatography The best initial approach to the separation of the carotenoid mixture is to carry out trial runs on silica gel layers using as developers increasing amounts of acetone in petroleum ether (40–60°C), e.g. 0, 5, 10, 20 and 40% v/v. This will immediately give an indication of the polarity of the compounds present and provide guidelines for further work. Where separations are reasonable but there is overlap, a new chromatogram based on the best acetone percentage should be developed with approximately half of that percentage of *tert*-butanol. If normal-phase methods fail or if there is a preponderance of polar compounds, reversed-phase separation should be tried; possible systems are indicated in Table 1. Where single development is insufficient to provide separation, the various zones can usually be scraped off the plate and re-extracted with good recovery rates provided that the process is done quickly and with due care. Separation within the various zones can then be carried out by renewed chromatography with appropriate solvent mixtures, i.e. solvents giving R_F values of about 0.50.

Identification Relatively few carotenoid standards are available commercially, but a large number of natural sources are well documented, and the monographs of Goodwin from 1980 and 1984 are particularly useful sources for this information. Otherwise, many carotenoids can be identified even in small

quantities from their visible light absorption spectra and by microreactions.

Chlorophylls

The chlorophylls are essential for photosynthesis and are thus of universal distribution in photosynthetic organisms. They are tetrapyrroles with a cyclic structure, and in intact tissue occur coordinated to a magnesium (2+) ion. The main pigments, chlorophylls *a* and *b*, differ only in having one methyl substituent in chlorophyll *a*, replaced by a formyl group in chlorophyll *b*. The intact chlorophylls also contain a phytol group which confers a hydrophobic moiety on an otherwise hydrophilic structure (see Figure 3 for structures for chlorophylls *a* and *b*). Chlorophylls *a* and *b*, which absorb light in both blue and red spectral areas, are green in colour, the former being described as blue-green and the latter as yellow-green.

**Figure 3** Structure of chlorophylls.

Table 2 Thin-layer chromatography of chlorophylls and derivatives (R_F values)

Chlorophyll derivative	R	R'	Magnesium	Colour	System 1	System 2
Pheophytin <i>a</i>	CH ₃	Phy	No	Grey	0.93	0.40
Pheophytin <i>b</i>	CHO	Phy	No	Yellow-brown	0.88	0.33
Chlorophyll <i>a'</i>	CH ₃	Phy	Yes	Blue-green	0.80	0.31
Chlorophyll <i>a</i>	CH ₃	Phy	Yes	Blue-green	0.76	0.27
Chlorophyll <i>b'</i>	CHO	Phy	Yes	Yellow-green	0.60	0.25
Chlorophyll <i>b</i>	CHO	Phy	Yes	Yellow-green	0.57	0.22
Pheophorbide <i>a</i>	CH ₃	H	No	Grey	0.36	
Pheophorbide <i>b</i>	CHO	H	No	Yellow-brown	0.18	
Chlorophyllide <i>a</i>	CH ₃	H	Yes	Blue-green	0.08	
Chlorophyllide <i>b</i>	CHO	H	Yes	Yellow-green	0.05	

Structures may be derived from Figure 3 (Phy = phytyl). System 1: cellulose layer (0.1 mm, Merck Art. 5716), light petroleum (40–60°C)–acetone (80 : 20). System 2: silica gel 60 (0.25 mm, Merck Art. 5721), diethyl ether–acetone–isooctane (20 : 20 : 60). All compounds show red fluorescence under UV light.

The relative amounts of chlorophylls *a* and *b* found in higher plants vary according to the species being investigated and prevailing light conditions, a ratio of about 3 : 1 being normal, while the ratio increases in plants growing in sunny situations and decreases in those found in shade. The C-10 epimers, chlorophylls *a'* and *b'*, which co-occur with the main chlorophylls in extracts, are now believed to be present in intact tissue. Other compounds often found in extracts are pheophytins *a* and *b* which differ from the parent chlorophylls only in lacking the magnesium ion, and the pheophorbides where the phytyl chain too has been lost. In addition, the very polar chlorophyllides which are simply derived by hydrolysis of the phytyl ester function in chlorophylls *a* and *b* are often present in small amounts. The pheophytins, pheophorbides and chlorophyllides are regarded as decomposition products produced during extraction.

Water-miscible solvents such as methanol and acetone are normally used for extraction of the chlorophylls which is often carried out in the presence of sodium carbonate to ensure neutralization of acidic impurities. Great care is also required during extraction to avoid undue exposure to heat or light as these lead to increased structural alteration. The extracted pigments are transferred to diethyl ether for concentration and analysis. Chlorophylls can be purified as their readily formed and moderately stable dioxane complexes.

Chlorophylls are normally applied to either cellulose or silica gel thin layers as acetone or diethyl ether solutions. Retention behaviour for illustrative systems may be found in Table 2, where structural parameters are also indicated. A densitometric trace obtained after chromatography of parsley chlorophylls can be found in Figure 4. In all cases the chlorophyll *a* derivative is less retained than the *b* derivative, an expected result of the presence of the

additional aldehyde function in the latter set. While loss of the magnesium ion leads to a reduction in polarity, loss of the phytyl group has the opposite effect. The chlorophyllides which lack the lipophilic phytyl chain remain close to the baseline in these systems.

Extraction The tissue being examined is mixed with 5 volumes of acetone containing small amounts of sodium carbonate, and macerated in a laboratory mixer for 2–3 min. This procedure is repeated until the matrix is colourless. The extracts are combined and concentrated to small volume under reduced pressure, 5% aqueous sodium chloride is added (to increase ionic strength and lessen the solubility of the pigments in the aqueous phase) and the resulting mixture is ex-

Figure 4 Densitometric trace (fluorescence, excitation at 366 nm, reflectance mode) of a chromatogram of chlorophyll pigments and derivatives obtained from parsley (*Petroselinum crispum*). Cellulose layer (0.1 mm, Merck Art. 5716), light petroleum (40–60°C)–acetone (80 : 20). Identification of zones: 1, pheophytin *a*; 2, pheophytin *b*; 3, chlorophyll *a'*; 4, chlorophyll *a*; 5, chlorophyll *b'*; 6, chlorophyll *b*. Minor zones are not identified.

Figure 5 Flavone skeleton showing standard numbering.

tracted repeatedly with similar volumes of diethyl ether. The diethyl ether extracts are combined and taken to dryness under reduced pressure at less than 40°C. The dried material can now be dissolved in fresh diethyl ether for application to the thin-layer plates.

Identification All chlorophyll derivatives show a bright red fluorescence under UV ultraviolet light. Chlorophylls *a* and *b* are commercially available, but can be readily obtained by extraction as described above from spinach. Pheophytins can be prepared by treating diethyl ether solutions of the parent chlorophylls for 2 min with 13% hydrochloric acid. The use of more concentrated acid (30%) leads to the production of the pheophorbides. Chlorophyllides can be obtained if required by enzymatic hydrolysis of the chlorophylls themselves.

Flavonoids

The major classes of the yellow flavonoids are the flavones and flavonols and these will be discussed here. In the next section, the red-blue anthocyanins will be treated. The minor flavonoid classes can in most cases be investigated by similar systems to those described here for flavones and flavonols. The flavonoids are widely distributed in the plant kingdom and are said to occur in all vascular plants. Flavonoids can occur either as the aglycones or more usually as glycosides; the number of known glycosides of quercetin, for example, is in excess of 100.

The flavonoids are made up of two phenyl rings connected by a 3-carbon unit; the various classes are defined by the nature of the bridging unit between the two aromatic systems. The basic flavone structure and the numbering of the skeleton are given in **Figure 5**. Flavonols are regarded as a separate class although they differ from the flavones only in having a 3-hydroxyl group. The normal positions for oxygenation in these compounds are at 5 and 7 in the condensed system (ring A) and at 3', 4' and 5' in ring B.

Flavonoids are readily extracted from plant tissue by maceration in warm methanol and methanol–water mixtures. Where flavonoids are present as glycosides, additional information is to be had by

Table 3 Thin-layer chromatography of flavonoid glycosides (R_F values)

System: Silica Gel 60 F₂₅₄ (0.25 mm, Merck Art. 5715) with developing solvent: ethyl acetate–formic acid–acetic acid–water (100 : 11 : 11 : 27). Sources: a, *Anthemis nobilis*; b, *Crataegus monogyna*; c, *Petroselinum* spp.; d, *Saponaria officinalis*; e, *Diosma crenulata*; f, *Menyanthes trifoliata*; g, *Astragalus* spp.; h, *Betula* spp.; i, *Equisetum arvense*; j, *Ruta graveolens*; k, *Calendula officinalis*; l, *Myrica rubra*; m, *Primula sinensis*; n, *Camellia sinensis*. glu, glucoside; rut, rutinoside; gal, galactoside; rha, rhamnoside.

subjecting them to acid hydrolysis which only C-glycoside links survive. The products are recovered, dissolved in organic solvent and then subjected to chromatographic analysis.

While a large number of systems can be used to analyse the glycosides, experience suggests that adequate separations can be obtained on silica gel with a solvent systems containing ethyl acetate–formic acid–acetic acid–water in the proportions 100 : 11 : 11 : 27 v/v. Visualization is accomplished by spraying with a 1% diphenylborinic acid ethanolamine ester (Natural Product Reagent A) solution in methanol and thereafter with polyethylene glycol (PEG 4000). The plates are examined under ultraviolet light (366 nm) and the compounds are seen as spots in various yellow-orange-brown-green hues. Table 3 gives the chromatographic behaviour of some flavonoid glycosides with this system. It is apparent that the fact that the flavonols have an extra hydroxyl function does not give an immediately obvious increase in polarity. However, it should be borne in mind that the glycosidic substituent is found on the less exposed 3-position in the flavonols as against more exposed positions in the flavones. However, within each group it is apparent that increasing oxygenation increases polarity somewhat. Much larger

changes in polarity are observed on changing the sugar involved: the rhamnosides are less retained than the glucosides, which in turn are less retained than the galactosides. Unsurprisingly, the biosides and diglycosides are again more retained than the simple monoglycosides.

A wide variety of systems are available for the analysis of free flavonoid aglycones. Examples of such analysis using silica gel, polyamide and reversed-phase (RP 18) layers are given in Table 4. The detection system used is as for the glycosides. Here the trends are more readily seen, with increasing oxygenation, in particular the presence of additional hydroxyls, in general leading to increasing polarity. However, the presence of the 3-OH group in the flavonols opens the possibility of hydrogen bonding to the 4-keto group and thus a corresponding reduction in polarity. Correspondingly, while O-methylation normally reduces polarity, this effect is much reduced when the methylation is of the 3-OH group, since this again frees the keto group from intramolecular hydrogen bonding.

Extraction procedure The intact tissue is cut into small pieces and then macerated with 3 volumes of warm methanol for 2 min, and thereafter stirred for a few

minutes while heating to about 60°C. Filtration can be followed by a second extraction with a 1:1 mixture of methanol and water. The extracts are combined, the solvents removed and the pigments redissolved in methanol prior to application to the thin layers for separation.

Hydrolysis The dried extract is dissolved in equal volumes of methanol and 2 mol L⁻¹ hydrochloric acid and refluxed for 1 h. The mixture is then cooled and the aglycones extracted into diethyl ether or ethyl acetate. The resultant solution is taken to dryness under reduced pressure and then redissolved in fresh organic solvent prior to analysis. The sugars freed during this process remain in the water solution and these too may be analysed by thin-layer methods.

Identification A considerable number of flavonoid aglycones and glycosides are available commercially. Pure compounds can be isolated from established sources, many of which can be found in the monographs on flavonoid compounds given in the Further Reading section. In the absence of reference com-

pounds, observed polarities and the colours in ultra-violet light after treatment with diphenylboronic acid ethanolamine ester provide valuable evidence of identity.

Anthocyanins

The glycosidic anthocyanins are closely related to the flavonoid classes discussed above, sharing the same basic skeleton. They lack the 4-keto function and have the heterocyclic ring aromatized and thus occur as salts. They provide red-blue colours depending on the substitution pattern present. Only six aglycone anthocyanidins are usual and the structures of these are to be found in **Figure 6**. Both glycosides and aglycones are found in red to purple plant tissues in plants, and they are responsible for the familiar colours of many deep red fruits and fruit juices and red wine, as well as occurring in the leaves of many red-purple ornamental varieties of trees and bushes.

Since the anthocyanins are salts they must be extracted into acidic media. Methanol containing 1% concentrated hydrochloric acid is well suited, although if milder conditions are required, as for

Figure 6 Structures of the most usual anthocyanidins.

Pigment name abbreviations: Dp, Delphinidin; Pt, Petunidin; Cy, Cyanidin; Mv, Malvidin; Pn, Peonidin; Pg, Pelargonidin; glu, glucoside; rut, rutinoside; sam, sambubioside; sop, sophoroside; glurut, (2^o-glucosyl) rutinoside.

Sources: a, hydrolysis product; b, *Ribes nigrum* berry; c, *Vitis vinifera* fruit; d, *Fragaria* spp. berry; e, *Prunus* spp. fruit; f, *Rubus idaeus* berry; g, *Fuchsia* spp. flowers. Glycoside types are indicated as mono (monoglycoside), di (diglycoside), tri (triglycoside) and bioside (glycosylglycoside). R_F values are given for cellulose layers (0.1 mm, Merck Art. 5716), using for development mixtures of concentrated hydrochloric acid, formic acid and water as follows: system 1 (19:19:62), system 2 (7:51:42) and system 3 (25:24:51).

example when the sugar moiety is acylated, this may be replaced by methanol containing 5% acetic acid. After concentration, the solution can be directly subjected to thin-layer chromatography on cellulose.

The individual anthocyanins may be subjected to hydrolysis by refluxing in hydrochloric acid for an hour, after which time the liberated anthocyanidins are extracted into 1-pentanol. The solution is evaporated to dryness under a stream of nitrogen, then redissolved in methanolic hydrochloric acid. This solution can be used directly for chromatography.

Results obtained for the separation of anthocyanins and anthocyanidins on cellulose layers using hydrochloric acid-formic acid-water mixtures as developing solvents are to be found in Table 5. The major trends in the results are immediately obvious.

Looking first at the anthocyanidins it can be seen that polarity increases with the number of hydroxyls present, while the presence of methoxyls has a much smaller effect. Examination of the monoglucosides shows that while a considerable increase in polarity is observed as a result of glucosylation, the effect seen above is carried over to this group of compounds. The same trend is seen in the even more polar biosides where the rutinosides are ordered in the same way and in the diglucosides where cyanidin diglucoside is less polar than the corresponding peonidin derivative. The single triglycoside examined is, as expected, even more polar than the diglycosides. These general findings are well seen in the chromatographic results obtained on separation of the pigments from raspberry and blackcurrant fruits (Figure 7).

Extraction procedure The intact tissue is cut into small pieces and then macerated with 3 volumes methanol containing 1% concentrated hydrochloric acid for 3 min. The extract is decanted and retained, and the procedure repeated twice. The extracts are then collected together and an equal volume of petroleum ether (40–60°C) added. After shaking vigorously for 2 min the layers are separated and the aqueous extract re-extracted in the same way with a further portion of petroleum ether. The defatted extract is then dried under reduced pressure. The pigments are redissolved in methanolic hydrochloric acid for chromatographic analysis.

Hydrolysis The defatted extract is dissolved in equal volumes of methanol and 8 mol L⁻¹ hydrochloric acid and refluxed for 1 h. The mixture is then cooled and the free anthocyanidins extracted by shaking with 1-pentanol. The 1-pentanol layer is separated and the solvent is removed in a stream of nitrogen (35°C). The anthocyanidins are then redissolved in methanol containing 1% concentrated hydrochloric acid. The sugars freed during this process remain in the water solution and these too may be analysed by thin-layer methods.

Identification Anthocyanins are not readily available commercially and are best extracted freshly from established sources. The anthocyanidins are then readily obtained by hydrolysis as described above. The specialized flavonoid monographs suggested for further reading give long lists of suitable sources.

Other Pigments

A large number of other pigment groups occur in nature. Among the less polar and more abundant

Figure 7 Chromatography of anthocyanins from (A) raspberry (*Rubus idaeus*) and (B) blackcurrant (*Ribes nigrum*). Cellulose layer (0.1 mm, Merck Art. 5716) using for development a mixture of concentrated hydrochloric acid, formic acid and water (25:24:51). Identification of zones: 1, cyanidin-3-(2^G-glucosyl)rutinoside; 2, cyanidin-3-sophoroside; 3, cyanidin-3-sambubioside; 4, cyanidin-3-rutinoside; 5, delphinidin-3-rutinoside; 6, cyanidin-3-glucoside; 7, delphinidin-3-glucoside.

of these are the various quinones, which can be investigated by thin-layer chromatography, although no particular system seems to be useful for more than a small groups of compounds. Other compounds

which should be mentioned are the many groups of tetrapyrrole pigments, both cyclic and acyclic, but these are highly polar and individual chromatographic systems are again required for each type.

Future Trends

The popularity of thin-layer chromatography for the analysis of pigments seems likely to continue as interest in natural pigments as food colorants increases. The possibility of carrying out some 20 parallel analyses on a single plate in 1 h ensures that the method represents a good alternative to high performance liquid chromatography. The fact that thin-layer chromatographic systems are cheap and easy to use, that the results are immediately observable, and that the method is both rugged and transportable will probably lead to increasing applications in the production side of the food industry. Applications of this type would be expected to lead fairly rapidly to an increase in the relatively small number of specialized spray reagents presently available for work with pigments.

POLYCHLORINATED BIPHENYLS: GAS CHROMATOGRAPHY

D. E. Wells, FRS Marine Laboratory, Aberdeen, UK

Copyright © 2000 Academic Press

Introduction

From the initial detection of polychlorinated biphenyls (PCBs)* in biological tissue in the 1970s by Jensen there has been a continuous development in the analytical chromatographic techniques to determine these chemicals (Table 1). PCBs occur as complex mixtures which have a considerable impact on the cost of a complete analysis. Highly sophisticated techniques are required for the congener separation, and clean-up methods to prepare the samples tend to be labour intensive. Multi-residue methods in which several polyhalogenated hydrocarbons (PHHs) groups such as chlorobornanes (toxaphene), polychlorinated naphthalenes (PCNs), polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), polychlorinated diphenyl ethers (PCDEs) and their brominated homologues, can be determined in parallel are available, but this approach can lead to a compromise, resulting in lower recoveries and unresolved peaks in the chromatograms.

The first separation of PCBs was obtained using packed gas chromatographic columns with industrial formulations as calibration standards to quantify a single total value for the PCB. This early technology did not have the resolution to separate the PCBs into individual congeners and the most appropriate method to estimate these contaminants at that time was unquestionably by the summation of the peak heights or areas of the low resolution chromatogram. The continual development of sample preparation, chromatographic separation and the final determination has improved the reliability of the data in many laboratories. This has allowed a more detailed interpretation of the data, including the toxic non-ortho chloro and mono-ortho chlorobiphenyls (CBs).

Of the 209 CBs, 132 have been measured in industrial formulations at or above the 0.05% level. The original selection of CBs, made by the European

Union Community Bureau of Reference in 1982, included CB 28, 52, 101, 118, 138, 153, and 180 and has now been adopted widely in many terrestrial, marine and food monitoring programmes. However this limited number of congeners was insufficient to study the specific toxicological effects and spatial patterns of these contaminants. These congeners, on their own, do not provide data for the TEQ† values needed for legislative or for environmental policy purposes.

The groups of toxic of CBs are:

Non-ortho CBs	CB 77, 81, 126, 169
Mono-ortho CBs (penta)	CB 105, 114, 118, 123
Mono-ortho CBs (hexa)	CB 156, 157, 167
Mono-ortho CBs (hepta)	CB 167

A schematic diagram of the isolation, separation, clean-up, group separation and final detection in environmental matrices in relation to the chromatographic separation of the congeners is given in Figure 1.

Sample Preparation for Gas Chromatography (GC)

The main difficulties for CB analysis are still the separation of these congeners (i) from other co-extractants both at the bulk level, e.g. lipids, (ii) from other trace contaminants, e.g. chlorobornanes (toxaphene) and (iii) from other interfering congeners, e.g. CB 77 and CB 110. With the present methodology it is now possible to measure individual CBs routinely at the pg kg^{-1} and with care at the fg kg^{-1} . Trace amounts of co-extracted materials such as lipids, wax esters and sulfur degrade the analytical chromatographic column which is both expensive and time-consuming to replace. Effective clean-up of the sample extracts is essential prior to GC and liquid chromatography (LC)-GC separation because traces of lipids (0.1 mg) will become significant if the final sample volume is reduced to ca. 100 μL .

Destructive clean-up methods are mainly alkaline treatment (saponification) or oxidative dehydration (sulfuric acid treatment). Alkaline treatment is similar

*The term 'Polychlorinated Biphenyl (PCB)' refers to the technical mixtures found in the formulation and the measurements made on the basis of calibration with these mixtures. *Chlorobiphenyl (CB)* refers to the individual congener named by the Ballschmitter number.

†TEQs refer to the sum of the concentration of the congener equivalent to 2, 3, 7, 8 TCDD obtained by using the toxic equivalence factor for each PCB.

Table 1 Chronological development of chlorobiphenyl analysis

<i>Year</i>	<i>Development</i>
1925	Large scale manufacture of PCB formulations.
1966	First reported measurement of PCBs as 'Avian Peaks'. Packed GC column separation of PCBs. Concentration in samples estimated against industrial formulations and summation of mixed component peaks in the chromatogram.
1969	Development of adsorption column chromatography for clean-up of biological tissue.
1975	Introduction of glass capillary columns. Improved separation of PCBs.
1970's	Development of stable GC evens and electronics to improve reproducibility of retention indices.
1980	Individual chlorobiphenyl congeners identified and systematically numbered. Introduction of fused silica capillary columns. Improved GC column stability.
1984	Retention times of all 209 CBs measured on an SE 54 capillary column.
1985	Reference materials, certified for individual CBs become available. Commercial availability of many of the 209 CBs. Reports of retention times on polar and semi-polar stationary phases. Development of multi-dimensional chromatography.
1988	Focus on the analysis of planar, toxic CBs and the application of toxic equivalence concentrations (TECs) for CBs as well as dioxins.
1989	Separation of CBs on the basis of their spatial configuration. Identification of all congeners present in main commercial formulations.
1989–1993	LC/GC coupled online. Development of multidimensional GC.
1990	Use of pyrenyl-silica HPLC for separation of non- and mono-ortho CBs.
1990's	Development and application of novel extraction techniques including accelerated solvent extraction, microwave assisted extraction, Soxhtec, supercritical fluid extraction.
1992	Expansion of retention data for 5 GC phases of different polarity for all congeners in commercial mixtures (> 0.05%), except CB 69, 75, 96 and 182; series coupled columns.
1993	SFE-GC coupled techniques.
1995	Improvements of pyrenyl-silica HPLC separation through temperature control.
1994/8	Use of pyrenyl-silica column for separation of CBs and PCDD/Fs.
1997/9	Modular multidimensional gas chromatography.

to the saponification used in conjunction with extraction, but is applied sequentially to the solvent extraction instead of applying it to the matrix directly.

Non-destructive methods use solid-phase columns, gel permeation techniques and dialysis. Alumina columns are very effective and probably one of the most frequently used clean-up methods. Silica and florisil columns are alternative adsorbents. Gel Permeation Chromatography (GPC) or size exclusion chromatography (SEC) has also been used for lipid removal and for separation based on molecular size. SX-3 Bio Beads are used in most cases. Dialysis techniques include the use of a polythene film of pore size ca. 50 μm . The CBs migrate from the fat through the polythene tube to the cyclohexane solvent surrounding the tube. Dynamic dialysis inside a Soxhlet gives a recovery of over 95% in 8 h. The rate of dialysis is temperature dependent with the optimum temperature being around 43°C, above which the lipids are also dialysed at an unacceptable rate. Sulfur must be removed from the sample extracts by percolation through an activated copper column, since the element is sufficiently soluble in organic solvents and, in large quantities, can completely saturate the detector signal, particularly the ECD.

Group Separation

Group separation of the CBs is necessary (i) to separate the non-ortho CBs and the mono-ortho CBs that occur at relatively lower concentrations, e.g. CB 105, CB 156 from the other congeners, (ii) to remove other interfering PHHs and (iii) to remove further traces of co-extracted material remaining from the extraction of the bulk matrix.

Silica gel columns containing 1–2 g of adsorbent are frequently used to obtain such a pre-separation. The CBs and chlorobenzenes are eluted with a non-polar solvent (hexane or iso-octane) in the first fraction. Other sorbents such as florisil have also been used.

The isolation of the non-ortho CBs is based primarily on the planarity of the molecule compared with the ortho CBs, and as such these congeners tend to be separated along with other planar PHHs. There are three techniques used to fractionate PCDDs, PCDFs and planar CBs. These methods use gravity carbon columns, HPLC with graphitized carbon columns and HPLC with PYE [2-(1-pyrenyl) ethyl dimethyl silica] columns. Other HPLC column phases have been developed to isolate the planar contaminants from other PHHs including 2,4-dinitrophenyl mer-

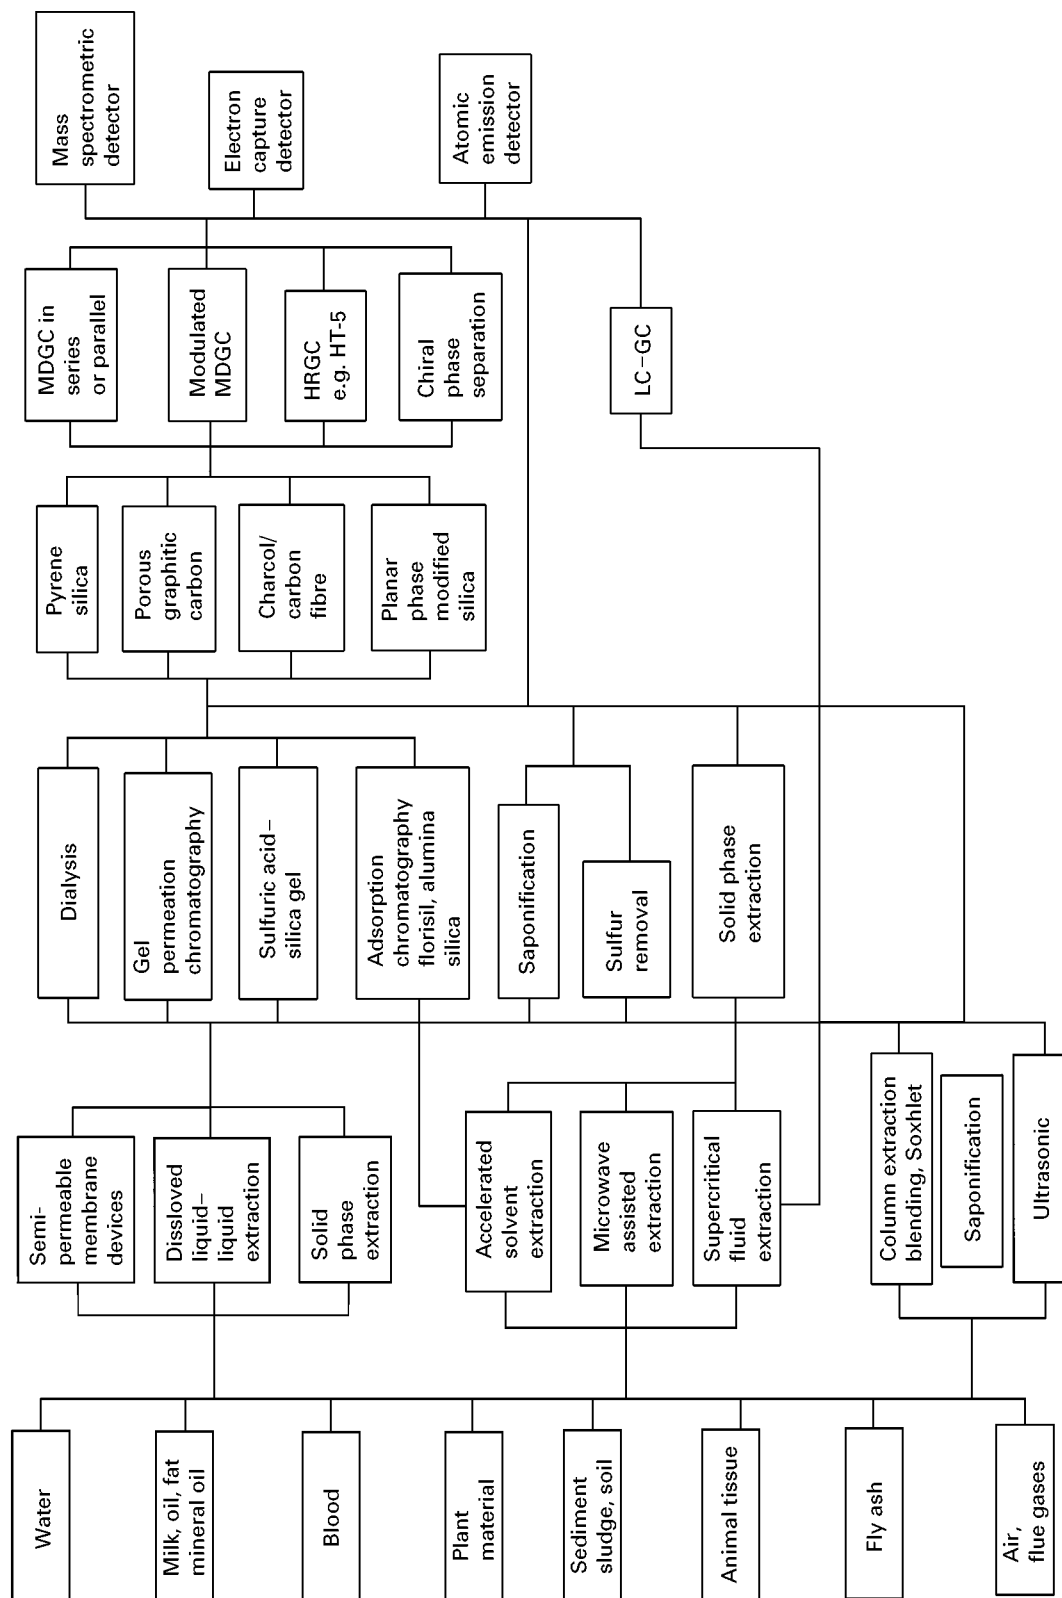

Figure 1 The schematic flow diagram of the analysis of chlorobiphenyls. The connecting routes show the types of environmental samples, the methods of extraction which are currently available, the clean-up techniques, the group separation, high resolution chromatographic separation and the range of detectors used for the final measurement.

Figure 2 The resolution between CB 138 and CB 163 on a pyrenyl-silica HPLC column, 250 × 0.46 mm. i.d. as a function of the column temperature. The maximum resolution occurs around 0°C. The column cooling was controlled by a solid-state Peltier heat pump.

captroparyl silica (DNMPM), dinitroanilinepropyl silica (DNAP) and tetranitrofluoriminopropyl silica (TENF). When the congeners are finally determined by GC, it is not necessary for them to be resolved from each other by HPLC.

The separation of CBs on the Comosil PYE column is temperature dependent (Figure 2). One of the more difficult separations between CB 138 and CB 163 on most GC columns* is possible on the PYE column providing that the column temperature is reduced to ca. 0°C. The porous graphitic carbon column to separate CB 77 and CB 110 along with the other non-ortho and mono-ortho CBs uses a double forward and reverse constant flow with hexane as an eluant.

LC-GC Combinations

Linking LC with GC aids the development of automated analysis and reduces the likelihood of contamination. There is also a substantial increase in the resolving power of 2D chromatography over a single system, especially where the polarity of the phases is orthogonal. The preferred combination of columns can sometimes be difficult because the polarity of the phases and the solvents used can make the linking difficult. Interfacing the LC to the GC has also been hampered by the relative volumes of the carrier fluids (liquids and gases). Rather than have a continuous flow-through system, we can overcome both difficulties in linking LC with GC by using the modulated approach by cryofocusing the eluate from the first column, removing the first solvent before flushing

onto the second column with an alternative fluid, i.e. a second solvent in the case of LC-LC, or by flash vaporizing into the carrier gas in the case of LC-GC.

Gas Chromatography

The chromatographic separation techniques for different congener groups is given in Table 2.

Sample Injection

There are three main injection techniques used in the analysis of CBs in environmental tissues, the splitless, the programmed temperature vaporizing (PTV), and the on-column injector. The splitless injector is used by most laboratories for CB analysis and must be optimized for splitter time, needle length in relation to the length and volume of the injector, and the type and cleanliness of the injection liner. The advantage of the on-column over the splitless injector is that the optimum conditions are more straightforward and there is less opportunity for mass discrimination over the range of CBs, primarily since all of the sample is injected onto the column. However, the sample must undergo a rigorous clean-up. Insufficiently cleaned samples seriously affect the column performance when using an on-column injector, whereas analyses with a splitless injector are less affected by non-volatile deposits. Only the glass liner requires regular, routine replacement.

Chromatographic Phases

Packed columns used in the 1970s and early 1980s have been replaced initially by glass and then by higher resolution, polyimide coated, fused silica cap-

*The separation between CB 138 and CB 163 can now be achieved using the HT5 stationary phase.

Table 2 Chromatographic separation techniques for different groups of congeners

Congener	Group

illary columns. Stationary phases of different polarities can be used for the determination of CBs, but non-polar and medium-polar phases generally offer a higher resolution.

A number of stationary phases tailored to the separation of CBs (Table 3) have shown considerable improvement over the more conventional proprietary phases available. These phases have had greater success in separating additional congeners when used in series with more conventional columns. A 1,2-dicarba-*closo*-dodecacarborane polydimethylsiloxane (HT-5) column has been used in series with a CPSil-8 (5% diphenyl polydimethylsiloxane) column with helium as carrier gas to separate 84 congeners using an electron-capture detector (ECD) (and

108 congeners using mass spectrometry detection (MS)). The HT-5 column has an upper temperature limit in excess of 300°C enabling fast temperature programming and analysis in less than 60 min. The HT-5 phase has been further optimized by using a 60 m × 0.25 µm i.d. fused silica column with a film thickness of 0.25 µm able to separate 106 congeners with ECD and 138 congeners with MS. This includes the separation of the critical CB 138/CB 163 pair. A prototype smectic liquid-crystalline polysiloxane column is able to separate some CB mixtures that have been more difficult to separate on more conventional columns such as CB 28/31 and CB 138/163. This phase is also useful to separate the non-ortho and mono-ortho CBs.

Multidimensional Gas Chromatography (MDGC)

Currently, all of the ca. 132 congeners detectable in formulations and environmental matrices cannot be separated on a single GC or HPLC column (Table 2). However, the separation power can be substantially increased when columns are coupled either in series or in parallel. The greatest separation is obtained by using different systems and/or phase types to maximize the orthogonality of the separations. Multiple columns such as serially-coupled columns parallel-coupled columns, two-dimensional GC and, recently, comprehensive multidimensional GC (MDGC) have been developed to provide greater resolution of complex mixtures such as CBs.

In two-dimensional GC co-eluting compounds are 'heart-cuts' as they elute from the first capillary column and are transferred to a second capillary column of a different polarity which is able to separate the isolated group of compounds. This technique offers a complete separation of certain groups of unresolved congeners which are 'heart-cut' from the first column. The technique is limited by the number of 'heart-cuts' which can be made in one chromatographic run, since more than three to four lead to peak overlap on the second column. Analysis times of the 'heart-cut' two-dimensional GC are also relatively long. Nevertheless this technique has been applied to the determination of CBs in environmental samples. The mono-ortho CBs 60, 74, 114, 123, 157, 167 and 189 have been determined in Aroclor mixtures and seal tissue using MDGC with ECD combining the Ultra 2 and FFAP columns. This direct method was found to be preferable to the separation of the mono-ortho CBs and the other congeners by HPLC. Either MDGC or off line HPLC separation of the mono-ortho CBs is often necessary to reduce the risk of false positive results from interferences since these congeners occur at relatively lower concentrations compared with the di- and tri-ortho CBs.

Comprehensive, modulation MDGC yields truly three-dimensional chromatograms (2D time base \times concentration). Two capillary columns are connected in series by a retention gap which can be heated very quickly in a reproducible way. The eluants from the first column are cryofocused in the retention gap for a period of ca. 3 min, after which time the retention gap, which has a minimum thermal capacity, is heated quickly to 'inject' the focussed compounds onto the second column of different polarity. The second chromatogram lasts for approximately the same period of time as the period of cryofocusing, so that a time series of 3 min chromatograms are produced to provide a two-dimensional separation (Figure 3). Because peaks collected at the

modulator are very highly focussed before they enter the second column, an extremely high sensitivity can be obtained in combination with a very high selectivity.

Chiral Separation

Of the 209 CBs, 78 display axial chirality due to the steric hindrance to free rotation about the C–C axis of the two aryl rings, and of these 19 possess 3 or 4 chlorine atoms in the ortho position. The CBs 84, 88, 91, **95**, 131, **132**, 136, **149**, 171, **174**, 183, and 196 are present in commercial mixtures; the four in bold type are present above the 2% level. GC separation of the 19 stable atropisomers have been made on the following columns:

- 2,3,6-Tri-O-methyl- β -cyclodextrin
- 2,3-Di-O-methyl-6-O-hexyldimethylsilyl- β -cyclodextrin
- 2-6-Di-methyl-3-O-n-pentyl- γ -cyclodextrin
- 6-O-tert-Butyldimethylsilyl-2,3-di-O-methyl- β -cyclodextrin
- tert-Butyldimethylsilylated- β -cyclodextrin.

The enantiopure CBs have been isolated by chiral HPLC. The (–) CBs 84, 132, 136, and 176 eluted before the (+) enantiomers while the order was reverse for CB 135 and 175. The enantiomers CB 95, CB 132 and CB 149 in Clophen A60 have been separated using MDGC to 'heart-cut' the congeners from the first column (DB-5) onto the second chiral phase, heptakis (2,3,6-tri-O-methyl)- β -cyclodextrin (Chirasil-Dex). However, to date none of the enantiomers have been shown to be specifically toxic or able to induce any observable biological effect.

Detection

The power of the GC separation, especially with the thin (0.1 μ m) film phases, must be matched by the sensitivity and the specificity of the detector to measure concentrations of CBs at the 10^{-12} – 10^{-14} level. These low levels of detection are required for the analysis of samples from relatively clean areas of the environment, for example the polar regions, oceanic and remote atmospheric samples. They are also required for samples obtained from small organs from single animals taken as part of biological effects studies or the investigative analysis of human adipose tissue.

Insufficient chromatographic resolution and incorrect calibration of the detector (Table 3) are still the primary source of error in the determination of CBs by GC. Errors associated with the calibration of the detector can be greatly reduced by implementing the

Figure 3 GC-ECD chromatogram of CB 77, CB 126, CB 169 showing the use of the Thermal Desorption Modulator (TDM). The first column was 24 m \times 0.2 mm i.d. 0.15 μ m SB smectic phase, 24 cm 0.1 mm i.d. 0.12 μ m CP Sil 8 TDM and a 5.3 \times 0.2 mm i.d. 0.33 μ m Ultra 2 second column. The TDM was desorbed every 3 min. (Reproduced from Geus H-J de, Boer J de and Brinkman UA (1997) *J. Chromatogr. 767*: 137–151, with permission, from Elsevier Science.)

following guidelines:

- only use certified solids or solutions. These are available for most congeners;
- confirm the identity of the material(s) provided by MS;
- control the preparation dilution and storage of calibrants by weight;
- store ampoule stock and working calibration solutions in a cool dark place. Avoid using screw top containers and do not store screw top containers in the refrigerator;
- confirm the purity of all solvents used by concentrating to ca. $\times 100$ and analysing with an ECD and an FID;
- calibrate the detector with sufficient frequency to ensure the response factor for each congener is ca. $< \pm 5\%$ of the actual response;
- check the frequency of calibration, which is a function of the cleanliness of the GC system;
- check new stock solutions against previous calibration solutions or against independent solutions of known quality.

A summary of the detectors which have been used for the determination of CBs is given in **Tables 4** and **5** along with the relative advantages, disadvantages, relative cost and current detection limits. ECDs were used initially because of their high sensitivity for electronegative compounds, but MS detection has become a routine method for measurement. Modern MS instruments are easy to operate, are more selective than the ECD, and have a better linear range.

Electron-Capture Detection

The most widely used detector for CB analysis is still the ECD. It is inexpensive, easy to use, highly sensitive and selective towards halogenated compounds containing one or more halogen atoms. Unfortunately the detector is not only sensitive to the number of

halogen atoms, but also to the spatial configuration of the molecules and its cross sectional area. This means that the detector response is specific not only to each congener, but also to its enantiomers, if they exist. The detector also has a small linear range, making it effectively non-linear requiring both constant and multi-level calibration, although the small (380 μL) frequency pulsed, constant current detectors have extended the linear range. Recently a micro-ECD with a cell size of ca. 150 μL has been developed to further improve sensitivity and linear dynamic range.

Mass Spectrometry

The mass spectrometric detector (MSD) is fast becoming the preferred alternative to the ECD. The simpler MSD and Ion Trap Detectors (ITDs) have been fully integrated with capillary GC and most instruments now have a fused silica column terminating inside the ion source of the MS. The ITD differs from other MS techniques in that the ions formed by ionisation are trapped electronically and then destabilized according to their mass and transferred to the electron multiplier outside the trap itself. The MSD is now a robust instrument and although it requires more specialist attention than the ECD, it does offer considerably more power in terms of sensitivity, selectivity and confirmatory analysis. The MSD has a much wider linear range than the conventional ECD used for much of the routine CB analysis.

The high resolution MS provides highly specific mass detection with resolution between 6000 and 10 000 provided by accurate mass marking with PFK at m/e 316.9824 to prevent mass drift. This not only offers a high specificity, but also considerably reduces the likely interference with other trace contaminants such as PCDDs and PCDFs.

A further advantage of MS is provided by the increased sensitivity of Negative Ion Chemical Ionization (NICI) with molecules containing more than four chlorine atoms. The sensitivity can be further

Table 4 Summary of methods of calibration

Type	Use/advantage	Misuse/disadvantage
Single point calibration	Semi-quantitative, screening technique, calibrant and sample within ca ± 5 -10% linear detectors	Inaccurate, especially at low concentrations. Not suited to the ECD
Bracketing standards	Small linear range of the ECD. MS detection	Extrapolation beyond the upper and lower limits
Multipoint calibration	Most accurate method for ECD. Requires quadratic or cubic spline type curve fit	Time-consuming in use, maintenance of calibration solutions
Labelled internal standards ^{13}C , ^2H	Mass spectrometric detector, compensates for all recovery losses	Not suitable for ECD. Does not give any information on the intrinsic efficiency of the method.

Table 5 Detectors used for the determination of CBs by gas chromatography

<i>Detector</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Detection level</i>	<i>Relative cost</i>
High resolution MS (HRMS)	Very high specificity and sensitivity. Provides spectral identification. Use ^{13}C labelled analogues	Highly specialized operation High capital and maintenance cost	Low ng kg^{-1}	Very high*****
Isotope dilution MS (IDMS)	Very high specificity and sensitivity. Provides spectral identification. Use ^{13}C labelled analogues	Highly specialized operation High capital and maintenance cost	$5 \mu\text{g kg}^{-1}$	Very high**
Low resolution (LRMS) quadrupole and MSD	Used primarily as an GC detector	Specialist operation Moderate capital and maintenance cost	CB 28 PCI $200 \mu\text{g kg}^{-1}$ NCI $700 \mu\text{g kg}^{-1}$ CB 80 PCI $253 \mu\text{g kg}^{-1}$ NCI $2.2 \mu\text{g kg}^{-1}$	High*****
Ion trap detector (ITD)	Used primarily as a GC detector	Specialist operation Low maintenance cost Own ITD MS library	Low $\mu\text{g kg}^{-1}$	Moderate*****
MS-MS	Separation of unresolved compounds in the MS itself	Specialist operation High capital and maintenance cost	Low ng kg^{-1}	Very high*****
Flame ionization detector (FID)	Simple and easy to use. Good linearity. Useful as a check on clean-up efficiency	Poor sensitivity and specificity.	0.5 mg kg^{-1}	Low*
Atomic emission detector (AED)	Response only dependent on elemental composition Robust and stable	Poor sensitivity	0.1 mg kg^{-1}	Moderate***
Electron-capture detector (ECD)	Very sensitive. Inexpensive. Directly coupled to GC	Only selective for electron capturing material like halogenated hydrocarbons Response dependent on molecular structure. Small linear range	$0.1 \mu\text{g kg}^{-1}$	Low*****

***** Very applicable.

* Not very applicable.

enhanced by operating in the selective ion monitoring (SIM) or multiple ion monitoring (MIM) modes as opposed to the total (full scan) ion current mode (TIC). The main disadvantage with using the MS in SIM or MIM is that the confirmatory power of the technique is considerably reduced. In this mode the CBs generate a strong molecular base peak with a limit of detection (LOD) of 40–100 fg. One of the main advantages of MS, in addition to sensitivity and specificity, is the ability to use ^{13}C labelled compounds as internal standards to compensate for losses during sample preparation, especially at the fg level. Using ^{13}C congeners reduces the need for extensive recovery experiments or having to apply recovery corrections in the method validation and improves the overall variance of the data. High resolution cap-

illary GC coupled with tandem MS-MS provide a very powerful separation technique both by the chromatography but also in the mass spectrometer itself. The MS-MS will separate components that are not resolved by a single GC-MS alone.

Atomic Emission Detector (AED)

The AED is a well established and widely used detector for elemental analysis. Although the AED has an excellent sensitivity for most elements, it has a low relative sensitivity for halogens. As a result it has tended to be overlooked as a detector for trace organic contaminants in favour of the ECD and more recently the MSD. The AED is relatively very stable and, in contrast to the ECD, has a common molar response for compounds of equal halogen content.

Commercial AED instrumentation, with a detection limit of ca. 250–400 pg, has been too insensitive for the determination of CBs in all but the most contaminated samples. Recent AED development has used a 350 kHz on-column RF plasma set at 837.6 nm for the CI emission operating at 350°C with He at 10 mL min⁻¹ as make-up gas and O₂ as the plasma dopant. The capillary column is positioned so as to sustain the plasma *inside* the end of the column. This 'on-column' configuration improves the detection limit by $\times 30$ and provides sufficient sensitivity to be compared directly with the ECD in the analysis of real sediment samples.

POLYCYCLIC AROMATIC HYDROCARBONS

Gas Chromatography

Introduction

Polyaromatic hydrocarbons (PAHs) constitute a very extensive and probably the most structurally assorted group of organic compounds. They are ubiquitous to the environment, and may well be the most widely studied class of environmental pollutants. Unfortunately, because of their diverse nature, there is no single nomenclature that describes collectively these compounds to everyone's satisfaction. Thus, one is likely to come across the terms polyaromatic hydrocarbons, polyaromatic compounds, polynuclear aromatic hydrocarbons or polycyclic aromatic hydro-

carbons in the scientific literature, even though all may actually be referring to this same class of chemicals. For the purpose of this article, PAH is used in the broadest sense possible, so that even those compounds that contain atoms other than carbon and hydrogen may be included in the discussion.

PAHs are formed primarily from the combustion of fossil fuels, with major sources being of anthropogenic origin, although bacteria and plants also contribute some PAHs to the environment. Interest in these compounds dates back to 18th-century England when it was suggested that scrotal cancer afflicting chimney sweeps could have been caused by substances present in soot from burning coal. PAHs were still unknown at that time, of course. It was only 150 years later, in the 1930s, that it was finally confirmed that soot contains benzo[*a*]pyrene and dibenz[*a,h*]anthracene, two PAHs with carcinogenic properties. Research into PAHs was given significant impetus by this discovery and, to this day, enormous interest is still focused on these compounds, not only in studies

Figure 1 Structures of some common polyaromatic hydrocarbons.

on chemical carcinogenesis, but also in analytical science, for which PAHs have become favoured test analytes. Befitting their status as important pollutants, the US Environmental Protection Agency has designated 16 PAHs as priority pollutants. **Figure 1** shows the structures of some common PAHs.

PAHs are found in a variety of environmental samples (airborne particulates, water, soil) and even in food cooked at high temperatures (grilled meats and fish, for example). Moreover, they are often present as complex mixtures containing dozens of components. It is therefore essential to analyse for PAHs in environmental and other samples to which the human population in particular may be exposed.

Why we need to identify and quantify PAHs in such samples is clear. Since many but not all PAHs are carcinogenic and/or mutagenic, and complex mixtures normally contain both types, the only way to assess the risks posed by those with high carcinogenic potential is to characterize them individually. Additionally, the type and variability of different combustion sources produce PAH profiles (in terms of the composition and quantities of the individual compounds) that are characteristic of their origins. For instance, motor vehicle exhaust fumes contain rela-

tively more benzo[ghi]perylene, coronene and cyclopenta[cd]pyrene than any other sources. Thus, careful examination of such profiles can help to identify the PAH source, and health control steps can be taken to reduce or even eliminate emissions from the particular source. To be able to provide accurate information on individual PAH components in complex mixtures, a technique with good separation capability is imperative. Coupled with its other advantages, such as reasonably fast analysis and sensitivity, gas chromatography is most appropriate for PAH separation. This article focuses on the application of gas chromatography to the separation of PAHs. Attention is placed on the use of capillary columns since analysis by packed columns of such complex mixtures is impractical.

General Considerations

To be separated by gas chromatography, compounds must be volatile and thermally stable within the range of temperature used in the analysis. In this respect, PAHs conform to the requirements, since those containing up to about 24 carbon atoms are amenable to analysis by the procedure. There are exceptions, of

course, since volatilities do vary, even for compounds with the same carbon number.

The value of high resolution gas chromatography for separating complex multicomponent PAH mixtures was first recognized in 1964. This was the first application of capillary column gas chromatography to PAHs. Today, this technique remains the most amenable, and therefore the method of choice, for separating these compounds. Fortunately, it has been ascertained that virtually all of the PAHs that have been found to be carcinogenic or mutagenic are also relatively volatile – thus, gas chromatography is the method of choice to analyse for them, especially if based on considerations of cost and ease of use.

The application of capillary gas chromatography to PAH analysis took a leap forward in the 1970s when several column pretreatment procedures were devised to overcome the problems associated with coating liquid phases on glass column wall surfaces. Columns coated by surface adsorption were not easily reproducible. For high efficiency separations the coating of the liquid phase should be a thin, uniform film; complete coverage of the surface is also essential to counter active sites which compromise chromatographic integrity. One way of achieving satisfactory surface modification was by acid-leaching the Lewis acids present in the glass used to manufacture columns; much improved chromatography was the result.

General improvements in gas chromatography in relation to high efficiency separations have gone hand-in-hand with PAH analysis. Mention was made above of these compounds being commonly used as test substances to evaluate new or improved analytical procedures. This is because of the interest in their carcinogenic properties, their widespread environmental occurrence and their availability as multicomponent standard mixtures.

An early illustration of the power of capillary gas chromatography for separating complex mixtures of PAHs was provided by work published in the mid-1970s. More than 20 PAHs, including sulfur-containing compounds, present in carbon black from petroleum feedstocks were separated on a capillary column coated with SE-52 (5% phenyl methylsilicone gum) stationary phase (Figure 2). Isomers and trace compounds not previously detected could be resolved.

Subsequent work further illustrated the excellent resolution capillary columns could offer when more than 100 PAHs (including alkylated compounds) isolated from airborne particulates were separated. Interestingly, isomers differentiated only by alkyl group positions could be well resolved.

Further improvements in PAH analysis have subsequently come in the form of newer stationary phases, especially those with increased thermal stability. Chemically bonded and cross-linked polymeric phases were introduced in the early 1980s, along with

Figure 2 Chromatogram of PAHs, including sulfur-PAHs (peak 9, benzo[def]dibenzothiophene; peak 11, benzo[a]dibenzothiophene) in extract of furnace black from petroleum feedstocks. (Reproduced with permission from Lee ML and Hites RA (1976) Characterization of sulfur-containing polycyclic aromatic compounds in carbon blacks. *Analytical Chemistry* 48: 1890–1893.)

columns made of fused silica. They allow analyses to be performed at elevated temperatures, in contrast to physically coated columns. These phases also have greater wettability characteristics, meaning that, even at high temperatures, their homogeneity is maintained, and they do not collapse into droplets. Chromatographic data are more consistent and reliable as a result of these improvements; this is an important consideration if information about composition and identity is needed from environmentally derived PAH samples.

Methylsilicone stationary phases have been most commonly employed for separating PAHs; these include SE-30, OV-1, OV-101 and SP-2100. Others that provide good performance, like SE-52, referred to above, are based on the same material. Some examples of these are SE-54 (1% vinyl, 5% phenyl methylsilicone), OV-3 (10% phenyl methylsilicone), OV-7 (20% phenyl methylsilicone) and OV-17 (phenylmethylsilicone). Of these, SE-52 and SE-54 have perhaps been the favoured stationary phases of most people working on PAH analysis. Commercial suppliers now list many phases under their own labels that are equivalent or nearly equivalent to those mentioned above and that are optimized for PAH analysis.

Liquid crystalline stationary phases have also played a role in the history of PAH analysis by gas chromatography. They offer the promise of separating closely related PAHs with greater efficiency than conventional stationary phases. The motivation for applying such phases was the complexity of PAH mixtures, especially in relation to isomers which differ significantly in their carcinogenic properties (e.g. benzo[*a*]pyrene which is carcinogenic and benzo[*e*]pyrene which is less so, and benz[*b*], [*j*] and [*k*]-fluoranthenes which possess a range of carcinogenic activities). Liquid crystal phases seemed to be most suited to packed-column gas chromatography since it was the latter (with conventional stationary phases) that lacked the capability to separate closely related components.

The rationale for using liquid crystal packings is that, in comparison to conventional phases they are better able to exploit slight structural differences in isomeric PAHs, thus enabling their resolution. Separation is based on relative permeation of differently shaped PAH between layers of the liquid crystals.

Despite demonstration of some impressive results with liquid crystal phases, the advent of capillary columns, coupled with improvements in conventional stationary phases, column treatment and column coating technologies have led to a slight loss of interest in these phases, not only for separating PAHs but also other analytes. (Such phases have been coated

onto capillary columns and are still sporadically utilized for PAH analysis.) The main disadvantages of these phases are that their properties tend to change over prolonged use, and long equilibrium times are needed between runs, although newer phases have higher thermal stabilities and tolerance. Additionally, PAH retention behaviour appears to be extremely difficult to predict, and expectations based on knowledge of retention of very similar PAHs are often at variance with subsequent experimental observations.

Applications

Some of the more important applications of gas chromatography to PAH analysis have been in atmospheric pollution studies. As heavy traffic densities and industrial pollution are a common feature in major cities of the world, the carcinogenic and mutagenic potential of airborne particulates in urban atmospheres has attracted increasing attention. PAHs are commonly emitted into the atmosphere adsorbed on particulate matter from major combustion sources such as motor vehicle engines via their exhaust systems, uncontrolled natural or deliberate burning of forests, wood and coal, refuse, domestic and industrial power and heat generation. The most convenient method of collecting particulate samples is by drawing contaminated air through a filter. The entrapped particulates are then extracted for their PAH content. Another popular method is to trap PAHs directly on adsorbents (e.g. polyurethane plugs), which are subsequently extracted. Various procedures of extraction include Soxhlet extraction with a suitable organic solvent, followed by additional clean-up steps to isolate the PAH fraction. Other, more rapid extraction methods such as supercritical fluid extraction, accelerated solvent extraction and microwave-assisted solvent extraction have been introduced, the latter in particular has become very popular in recent years.

Although the flame ionization detector (FID) is commonly used for PAH analysis, its universality of response and thus lack of selectivity dictate that after sample extraction careful and sometimes laborious clean-up procedures must be performed to isolate the PAH fraction before gas chromatographic separation. The electron-capture detector (ECD) has also been used for PAH analysis, and ECD-FID response ratios can be calculated and used to differentiate between PAH of similar structures. **Figure 3** shows a chromatogram of PAHs extracted from urban air-borne particulates, generated by the two detectors simultaneously. The FID (lower trace in the figure) and ECD (upper trace) complement each

Figure 3 Chromatogram of polyaromatic hydrocarbons from urban particulates generated from simultaneous (bottom) flame ionization and (top) electron-capture detection (FID and ECD). Peak identities: 1, Phenanthrene; 2, anthracene; 3, 3,6-dimethylphenanthrene; 4, fluoranthene; 5, pyrene; 6, benz[*a*]anthracene; 7, chrysene/triphenylene; 8, β , β -binaphthalene; 9, benzo[*j*] and [k]fluoranthene; 10, benzo[*e*]pyrene; 11, benzo[*a*]pyrene; 12, *o*-phenylpyrene. In: Bertsch W, Jennings WG and Kaiser RE (eds) *Recent Advances in Capillary Gas Chromatography*, pp. 477–490. Heidelberg: Dr Alfred Hüthig Verlag.)

other to provide more positive identification of the PAHs.

Increasingly, mass spectrometry as a gas chromatographic detector is assuming greater importance for most PAH applications because of its greater sensitivity in quantitative analysis (based on its selected ion-monitoring mode in which ions that are characteristic of particular components are monitored) and improved diagnostic power. Using mass spectrometry with less drastic ionization conditions (chemical ionization, negative ion chemical ionization, etc.), similar or isomeric PAHs can be identified with greater certainty, in contrast to electron impact ionization which normally cannot be used to differentiate between such PAH structures since they often give nearly identical mass spectra. In addition to FID, ECD and mass spectrometry, other detectors have been coupled to gas chromatography for PAH analysis. These include the Fourier transform infrared detector, the photoionization detector, the photometric detection and the nitrogen-specific chemiluminescence detector – all of which respond to certain elements or functionalities in compounds, and thus afford a measure of selectivity.

Particulates emitted from vehicles that use diesel fuel have been found to have significant mutagenic potential due to the presence of the nitro-PAHs such as nitropyrenes, nitrofluoranthenes, dinitropyrenes, hydroxynitropyrenes and acetoxynitropyrenes. Some evidence suggests that there may be some other as yet uncharacterized compounds pres-

ent in diesel particulates that are mutagenic but do not belong to the nitropyrene family. Evidence of diesel particulates having greater mutagenicity than other types of particulates normally found in urban atmospheres has also been reported, based on results of a study carried out in a Japanese city. Some previously unknown mutagens were detected and identified; these included PAHs containing NO₂ substituents as well as a nitrogen atom in the ring nucleus. The discovery of these compounds underscores the enormous complexity and diversity represented by the family of PAHs.

In recent years, the size of airborne particulates has become a major issue in the assessment of the health risks posed by these atmospheric pollutants. For example, smaller-sized particles can be transported over greater distances, since they take longer to settle, if at all, increasing their transboundary pollution potential. They are also more easily inhaled, and are therefore more hazardous to health. There has been research to determine the link between particle size with the PAH composition associated with it. If a link can be determined, the health effects of various-sized particles can be better understood and studied. This may allow more effective control of emissions of PAHs to be implemented, by focusing on the emission sources with which particular groups of PAHs are associated. The gas chromatograms of PAHs associated with particulates of sizes < 0.5 μm and > 7.2 μm are shown in Figure 4. It is observed that the two chromatographic profiles are significantly different.

Figure 4 Chromatogram of the aromatic fraction of urban particulates. Top trace: extract from particulates of size $> 7.2 \mu\text{m}$. Bottom trace: extract from particulates of size $< 0.5 \mu\text{m}$. Peak identities: A, Phenanthrene; B, anthracene; C, fluoranthene; D, pyrene; E, benzo[ghi]fluorene; F, 4(H)cyclopenteno[cd]pyrene; G, benz[a]anthracene; H, chrysene/triphenylene; I, benzo[b] and [f]fluoranthene; J, benzo[e]pyrene; K, benzo[a]pyrene; L, indeno[1,2,3-cd]pyrene; M, benzo[ghi]perylene; N, coronene; Sq = squalene. (Reproduced with permission from Aceves M and Grimalt JO (1993) Seasonally dependent size distributions of aliphatic and polycyclic aromatic hydrocarbons in urban aerosols from densely populated areas. *Environmental Science and Technology* 27: 2896–2908.)

The urban atmosphere is only one of the environmental classes in which information on PAH is of interest. Much work has been done, and is continuing, on industrial effluents, and workplace and indoor atmospheres. Interesting insights on indoor PAH pollution have resulted from studies carried out by gas chromatography. Emissions from home appliances such as natural gas space heaters and water heaters have been found to contain PAHs, including the oxygen, nitrogen and sulfur analogues. Such findings are significant because they draw attention to the PAH exposure faced by young children and non-working adults in domestic dwellings. The comment has been made that more attention should perhaps be focused on such indoor pollution by PAH by health authorities than hitherto. **Figure 5** shows a reconstructed total ion mass chromatogram for exhaust emissions

from home appliances using natural gas. Samples were collected on a main filter and a backup filter.

Another form of indoor pollution far removed from urban or suburban settings may also be important. In rural communities, wood, charcoal or coal combustion in open stoves is often used for cooking. In confined dwellings with little or no ventilation, exposure to the combustion products, including PAHs, represents significant risks. Indeed, in a rural commune in China, the women exhibited a high lung cancer mortality rate even though most of them were non-smokers. Using gas chromatography-mass spectrometry, researchers determined PAHs, alkylated PAHs and nitrogen PAHs in particulates collected in commune households during cooking, primarily performed by these women. In many other parts of Asia as well as in Africa, similar lifestyles are followed;

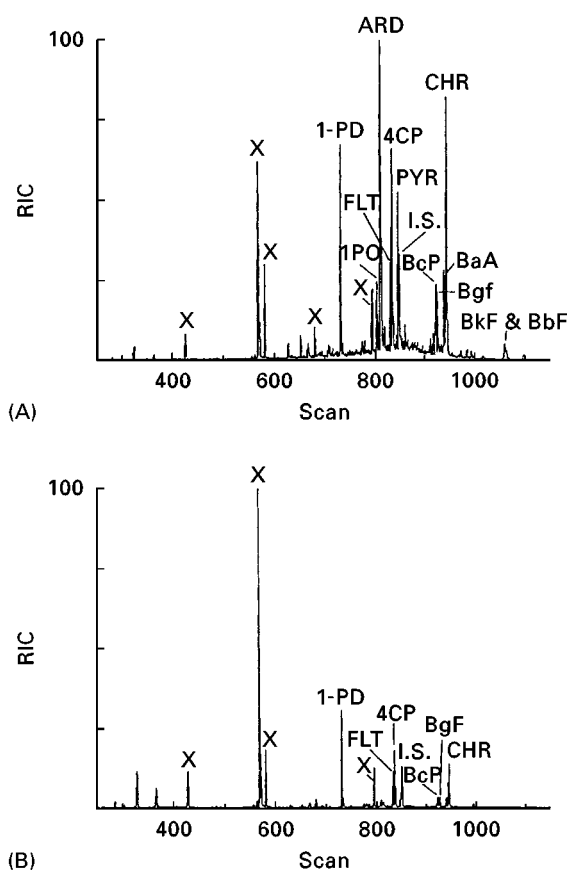

Figure 5 Total reconstructed ion current (RIC) or exhaust emissions from natural gas-fired home appliances: (A) fine particle front filter samples; (B) backup filter samples. Peak identities: I.S., internal standard ($n\text{-C}_{24}\text{D}_{50}$); 1-PD, co-injection standard (1-phenyldodecane); 1PO, 1*H*-phenalen-1-one; FLT, fluoranthene; ARD, cyclopenta[*def*]phenanthren-4-one; PYR, pyrene; BcP, benzo[*c*]phenanthrene; BgF, benzo[*ghi*]fluoranthene; BaA, benzo[*a*]anthracene; CHR, chrysene/triphenylene; BkF, benzo[*k*]fluoranthene; BbF, benzo[*b*]fluoranthene; X, contaminant. (Reproduced with permission from Rogge WF, Hildemann LM, Mazurek MA, Cass GR and Simoneit BRT (1993) Sources of fine organic aerosol, Part 5: natural gas home appliances. *Environmental Science and Technology* 27: 2736–2744.)

thus, indoor PAH pollution is a real threat that needs to be monitored more closely.

Notwithstanding the vast body of literature available on the use of gas chromatography for atmospheric PAH analysis, there has been a tremendous amount of work in other areas where information on these compounds is of interest. Capillary gas chromatography has been the major technique in the identification and determination of PAH mixtures in samples such as cooked foods, coal tar and creosote, soils and sediments, cigarette and marijuana smoke condensates, used engine oils and other oil products, carbon black, natural and contaminated waters in-

cluding rain and snow, marine organisms, petroleum products, asphalt, tyre particles and other rubber products, burnt plastics, coke, shale oils, biological sewage sludge, fly ash from incinerators, and soot from a variety of sources like forest and agricultural fires.

Concluding Remarks

Gas chromatography, particularly when used with capillary columns, has been the mainstay of separation techniques for the analysis of complex mixtures. The analysis of PAHs has virtually been intertwined with the technological progress of gas chromatography over the past few decades. Despite the introduction of other high performance separation methods such as liquid chromatography and supercritical fluid chromatography, gas chromatography has remained the technique of choice for separating PAHs in a large variety of samples. Although gas chromatography can be considered to be a mature technique, it is unlikely that its pre-eminent role in PAH analysis will be seriously challenged in the foreseeable future, even given the past and current tremendous pace of progress in analytical chemistry, particularly in separation science.

Polycyclic aromatic hydrocarbons (PAHs) are usually defined as a group of chemicals with two or more fused benzenoid rings. If elements other than carbon and hydrogen are present, the term polycyclic aromatic compounds (PAC) is used. PAHs are natural constituents of crude oil and many other petrochemical products and they are also formed by the incomplete combustion of organic matter. Therefore, they enter the environment from a wide variety of sources such as automobile emissions, industrial processes, waste incineration facilities, domestic heating systems and natural events such as forest fires and volcanic eruptions.

Natural sources of PAH emission have always existed but since the industrial revolution there has been a rapid increase in the loading of the environment with petrochemical PAHs and particularly with PAHs of pyrolytic origin.

The PAHs, both from natural and anthropogenic origins, are released into the atmosphere as vapour or adsorbed on to particles. They are then dispersed and transported long distances by wind before being deposited on the ground or in water, directly or in rain. PAHs are also present in water samples as a result of sewage from industries which use these compounds in their manufacturing processes (e.g. pharmaceuticals, explosives, plastics, synthetic dyes, pesticides and so on).

PAHs are one of the most contaminating groups of pollutants in the environment because of their mutagenic and carcinogenic activity. The activity of each compound depends on its chemical structure. Typically, environmental samples contain a complex mixture of various PAHs, including isomeric structures and both alkylated and nonalkylated PAH forms. **Figure 1** shows the structure of the 16 PAHs considered as priority pollutants by the US Environmental Protection Agency (EPA).

In PAH mixtures of petrochemical origin, two- or three-ring compounds are more abundant than the heavier PAHs, which have four or more rings. On the other hand a typical mixture from a high temperature combustion source contains mainly unsubstituted compounds and PAHs with four or more rings are more abundant than the smaller ones. So, PAHs in natural samples are always encountered as mixtures.

In the environment, PAHs may be eliminated or transformed to even more toxic compounds by chemical reactions such as photooxidation, sulfonation or nitration. For instance, pyrene, which is not mutagenic, can be transformed to nitropyrene, which is highly mutagenic, when nitrogen dioxide is present. In some conditions, traces of nitric acid in the nitrogen dioxide can also transform some PAHs into nitro-PAHs.

Because of their mutagenic and carcinogenic properties, PAHs have been determined in a variety of environmental matrices including air, water, soil, sludge and tissue. The European Community directive (98/83/EC) on the quality of drinking water established the global maximum admissible concentration of four PAHs (benzo(*b*)fluoranthene, benzo(*k*)fluoranthene, benzo(*ghi*)perylene and indeno(1,2,3-*c-d*)pyrene) as $0.10 \mu\text{g L}^{-1}$ and specified an individual value of $0.010 \mu\text{g L}^{-1}$ for benzo(*a*)pyrene. The World Health Organization (WHO) considers only benzo(*a*)pyrene with a reference value of $0.7 \mu\text{g L}^{-1}$.

Determination of PAHs

PAHs can be determined by high performance liquid chromatography (HPLC), gas chromatography (GC), supercritical fluid chromatography (SFC) and capillary electrophoresis (CE), but the preferred method is reversed-phase HPLC.

In GC, the most usual detection systems are flame ionization and mass spectrometry, with the latter becoming increasingly common. However, GC is unable to determine the nonvolatile and high molecular mass PAHs. SFC has also been used; its main advantages are its high separation efficiencies and short analysis times. UV-visible, fluorescence or mass spectrometric detectors can all be used.

Micellar electrokinetic capillary chromatography (MEKC) or cyclodextrin-modified CE are capable of separating all 16 PAHs in under 20 min. Despite the advantages in resolution power, the main drawback of MEKC is its poor concentration sensitivity, but this can be partially solved by using a fluorescence detector.

HPLC with a diode array detector enables the UV-visible spectra to be compared and is quite often used to determine PAHs. Fluorescence detection is the most suitable because of its higher sensitivity, although a few PAHs – for instance, acenaphthylene – do not show fluorescence. Spectrofluorimetric

Figure 1 Chemical structure of the 16 PAHs considered to be priority pollutants by the US EPA.

detection and wavelength programming enable each compound to be detected at its maximum emission wavelength and so sensitivity and selectivity can be improved. If a micellar mobile phase is used instead of an aqueous–organic one, lower concentrations can be detected. Other detection techniques, such as amperometry, have also been used and the limits of

detection are lower than those obtained with UV detection.

Sample-handling Techniques

Because of their toxicity and the low levels to be determined, PAHs are determined in various kinds of

samples which usually require treatment before chromatographic determination. For solid samples, such as soils, sludge, sediments and tissues, the classical Soxhlet extraction is still used, but the extraction is tedious and time-consuming. Other newer techniques, such as supercritical fluid extraction, microwave-assisted solvent extraction and ultrasonic extraction, have proved to be suitable for extracting PAHs and the times required are considerably less. Some of these techniques are followed by a clean-up step, usually performed by solid-phase extraction.

For gaseous samples, different kinds of adsorbents are used to retain the PAHs. PAHs associated with particulate matter are usually collected on filters and then vaporized and PAHs in the vapour phase are trapped by a back-up solid sorbent. Samples are desorbed using Soxhlet apparatus, ultrasonication or supercritical fluid extraction. Sample clean-up is usually required and performed by solid-phase extraction.

Liquid-liquid extraction is gradually being replaced as a technique for extracting organic compounds from liquid samples because it uses considerable amounts of toxic solvents. In this respect, solid-phase extraction has been shown to give good results. Other techniques, such as closed-loop stripping or supercritical fluid extraction, alone or after the solid-phase extraction of the aqueous sample, also give good results. For water samples, results are better when supercritical fluid extraction is applied after solid-phase extraction and not when supercritical fluid extraction is applied alone.

Solid-phase Extraction

In the determination of PAHs, solid-phase extraction is mainly applied to liquid samples but, as already mentioned, it is also applied in the clean-up step with gaseous or solid samples after other extraction techniques. The following discussion mainly refers to the analysis of aqueous samples but some references will be made to other kinds of samples.

Several kinds of sorbents in a variety of devices (e.g. cartridges or discs) may be used for the solid-phase extraction of PAHs. Solid-phase extraction is usually carried out in the offline mode but the online mode does have some advantages and recently has been increasingly used. Solid-phase extraction has been coupled to HPLC and also to GC and SFC to determine PAHs.

One of the most recently developed techniques for extracting PAHs is solid-phase microextraction (SPME) where the sorbent is coated on to a fused-silica fibre mounted in a syringe-like device. SPME is

a solvent-free technique, which is its main advantage, but it also has disadvantages compared to SPE.

Addition of Solvent or Micellar Media to Aqueous Samples

The solid-phase extraction of PAHs may seem to be a simple process because of their high hydrophobicity and because there are no expected breakthrough problems. However, the low solubility of the PAHs, which decreases as molecular weight increases, does present a problem. There may also be sorption problems during sampling and storage and to avoid these problems, it is necessary to increase their solubility. Normally this is done by adding organic solvents, such as acetonitrile, methanol and 2-propanol, or surfactants to the sample as solubilizers. The percentage of this solvent in the samples is a critical parameter because if it is low it may not be enough to solubilize the high molecular weight PAHs, whereas if it is high, the breakthrough volume will be low for the low molecular weight PAHs. Therefore, for each kind of sample, solid-phase extraction sorbent and organic solvent, this parameter must be optimized. Typical values are between 10 and 25%, depending on the solvent added and the sorbent used. **Table 1** shows the influence of 2-propanol on the PAH recoveries. The higher the percentage of 2-propanol, the lower the recovery of low molecular weight PAHs, whereas the higher the percentage of 2-propanol, the higher the recoveries of high molecular weight PAHs.

Surfactants have also been used instead of organic solvents. Surfactant molecules are amphiphilic, and have a polar and nonpolar moiety. Because of their amphiphilic nature, surfactant molecules can dissolve in water as monomers, or form a micelle with other surfactant molecules. The concentration at which they start to form micelles is termed the critical micelle concentration (CMC). The CMC depends on factors such as the surfactant itself, temperature, ionic strength and the presence of organic additives. It is the concentration at, or concentration range over which, solution properties like surface tension show an abrupt change in value. To solve the problems arising from the low solubility of PAHs in water and their adsorption on surfaces, surfactants such as sodium dodecyl sulfate (SDS; anionic type, molecular mass 288 and $8.3 \times 10^{-2} \text{ mol L}^{-1}$ CMC), cetyl trimethylammonium chloride (CTACl; cationic type, molecular mass 320 and $8.0 \times 10^{-4} \text{ mol L}^{-1}$ CMC), Brij-35 (neutral type, molecular mass 1182 and $1.0 \times 10^{-4} \text{ mol L}^{-1}$ CMC), have been used, among others. The concentration of surfactant significantly affects the recovery of the PAHs, as shown in **Table 2**, where the influence of the surfactant concentration on PAH recovery is demonstrated.

SDB, styrene-divinylbenzene. RSD, relative standard deviation.

Sorbents

For aqueous samples, C₁₈-bonded silica is mainly applied, although good results can also be obtained with styrene-divinylbenzene (SDB). Some authors claim that results are best when different sorbents are combined. For example, in the analysis of drinking

water samples, the best results are obtained from combined octadecylsilane (C₁₈)-ammonia (NH₂) solid-phase cartridges, whereas PAHs from soil samples were best extracted with silica (Si)-cyano (CN) or C₁₈-CN combinations.

One group of researchers compared three different bonded silica sorbents, C₁₈, cyano and phenyl, and demonstrated that results are best for C₁₈-bonded silica. Results are shown in Table 3, where CH₃CN and CH₂Cl₂ are used as organic solvents to elute PAHs.

The chromatographic system to be used must also be taken into account. It has been demonstrated that, to determine PAHs by HPLC-fluorescence in lake sediments, C₁₈-bonded silica and silica columns could be used satisfactorily in the clean-up and preconcentration step. However, they could not be used with GC-mass spectrometry (GC-MS) for PAHs greater than chrysene, due to interference from aliphatic waxes.

Another group tested various specific sorbents such as Chromspher II, a diol-treated porous glass chemically modified with a copper phthalocyanine trisulfonic acid derivative (Boos glass), a diol-modified silica with the same copper compound (Boos silica) and a copper phthalocyanine trisulfate-modified polymethacrylamide. It was shown that the second material (Boos silica) was quite useful for the trace enrichment of PAHs containing three or more fused benzene rings but for the smaller PAHs, conventional C₁₈-bonded silica gave better results.

Figure 2 shows chromatograms obtained in the analysis of 10 mL of surface water spiked with PAHs using Boos silica, Chromspher Π and C_{18} -bonded silica pre-columns. The Boos silica gives the cleanest chromatogram but has lost the two most volatile compounds.

Apart from the sorbents already mentioned, other sorbents such as Florisil (SiO_2 and MgO) can rapidly and efficiently recover PAHs for petroleum and sediment extracts as a clean-up step after another extraction technique.

Solid-phase extraction is widely used after the ultrasonication extraction or microwave extraction of soils and sediments, as a clean-up step before chromatographic determination. In these cases,

Florisil or C_{18} -bonded silica are the sorbents which are most used. SPE is also used before supercritical fluid extraction to analyse aqueous samples and results are better with solid-phase extraction-supercritical fluid extraction than with supercritical fluid extraction alone. Table 4 shows the results obtained when different extraction techniques were applied to determine PAHs in water samples. Much better results can be seen when solid-phase extraction technique is added to the supercritical fluid extraction one.

Most of the sorbents are used as cartridges but membrane discs can also be used to concentrate PAHs; the main advantages of discs are the considerable reduction in extraction time and the higher sur-

face of extraction, which means fewer clogging problems for the sorbent. They also enable larger volumes to be extracted with the same amount of sorbent than when cartridges are used.

Two different membranes, C₁₈-bonded silica and SDB were studied to determine PAHs from surface water. Prior to the extraction procedure, the discs were conditioned to prevent interfering peaks in the chromatogram. In this process, for C₁₈ discs, 20 mL of organic elution solvent (dichloromethane-ethyl acetate-acetonitrile, 50 : 30 : 20 v/v/v) was added to the filtration reservoir and slowly drawn through the discs by applying a slight vacuum. After drawing air through the discs for 5 min, 20 mL of an acetone-water mixture (80 : 20 v/v) was added and slowly drawn through the filtration discs, followed by 10 mL of Milli-Q water. The styrene-divinylbenzene copolymer discs were conditioned with 20 mL of acetone, 20 mL of acetonitrile and 20 mL of dichloromethane. After each addition a vacuum was applied to remove interfering compounds from the discs. Then, 20 mL of Milli-Q water was added and drawn through the disc before sample preconcentration.

Table 1 shows the recovery values obtained when C₁₈-bonded silica and SDB membrane discs were used in the determination of PAHs. In this case, 100 mL of Milli-Q water spiked with 0.5 µg L⁻¹ of 15 PAHs and 29 µg L⁻¹ of acenaphthylene were concentrated and

then eluted twice with 15 mL of organic mixture. In this table the influence of adding 2-propanol to the sample is also shown, as already mentioned.

Another group studied the solid-phase extraction of PAHs in water samples using solid-phase extraction discs with a glass fibre matrix (GFM) and recoveries were good for the six PAHs studied. The main advantage of this GFM sorbent is the high speed of extraction, and the lower amount of solvent required compared with the conventional cartridge. **Figure 3** shows the chromatograms of analysis of seawater and riverwater using this kind of membrane.

Other selective sorbents, immunosorbents, based on antigen-antibody interactions, have also been used for selective isolation of PAHs from complex environmental samples. The extraction of the PAHs from sediments by sonication with dichloro-methane-methanol, subsequent extract dilution with water and extraction with an anti fluorene immunosorbent gave similar results to those obtained with conventional clean-up procedures but selectivity was higher.

Desorption Solvent

After cleaning and conditioning the SPE cartridges or discs, the sample, with an organic solvent or micelle medium added, is applied. Then, organic solvents such as acetonitrile, tetrahydrofurane, acetone, *n*-hexane, methylene chloride, ethyl acetate and ethyl ether or mixtures of them are used to desorb PAHs.

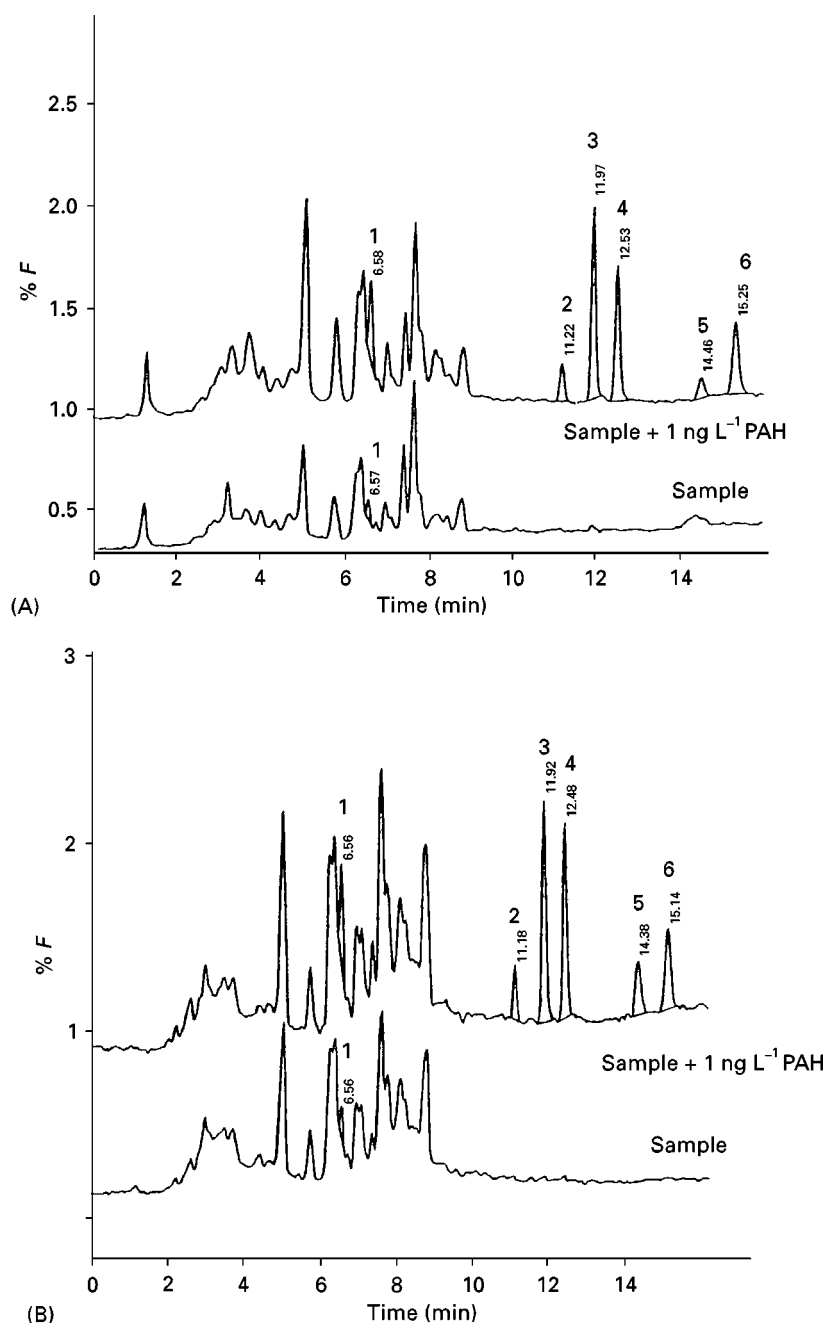

Figure 3 Separation and recovery of PAHs in (A) seawater and (B) riverwater, after being spiked with 1 ng L⁻¹ for each compound, except fluoranthene (10 ng L⁻¹) and indeno[1,2,3-*cd*]pyrene (5 ng L⁻¹) to 1 L of sample. Peak assignment: 1, fluoranthene; 2, benzo[*a*]fluoranthene; 3, benzo[*k*]fluoranthene; 4, benzo[*a*]pyrene; 5, benzo[*ghi*]perylene; 6, indeno[1,2,3-*cd*]pyrene. Reproduced with permission from Urbe and Ruana (1997).

Recoveries of the low molecular weight PAHs are higher with nonvolatile solvents, but the recoveries for most of the PAHs with 4–6 aromatic rings are higher when a nonpolar solvent is used. So, in order to ensure optimum recoveries of all the PAHs, mixtures of solvents are usually recommended.

If the solvent used is compatible with the chromatographic system, concentration of the ex-

tracts is usually required to lower the limit of quantification. If the solvent is not compatible with the HPLC system, the extract obtained is dried with sodium sulfate evaporated at room temperature under a current of nitrogen or with a rotary evaporator and the residue dissolved in the mobile phase. The volume of organic solvent used in the solid-phase extraction membrane system is usually bigger than the volume

used in a cartridge system (between 30 and 50 mL and 1–5 mL, respectively).

Online Solid-Phase Extraction Chromatographic System

The main advantages of online systems are that the samples have to be manipulated less, they reduce analysis time and they consume less organic solvent.

SPE-HPLC is the most straightforward coupling method and therefore the most used. The sample preparation and conditioning steps are similar to those used in the offline but only the mobile phase is required to elute the compounds retained in the pre-column which is connected online to the analytical column.

The most used sorbents are the C₁₈-bonded silicas and SDB, although other specific sorbents can also be used. Depending on the sorbent and the solvent added to the aqueous sample, some interfering peaks can appear in the chromatogram, even when fluorescence detection is used. For instance, MeOH, acetonitrile and 2-propanol were tested as organic modifiers in the analysis of 50 mL of Milli-Q water with 15% of organic solvent by online solid-phase extraction with SDB discs. In this study, when using MeOH, peaks at the same retention time as naphthalene, phenanthrene, fluoranthene and pyrene appeared in the chromatogram. 2-Propanol gave peaks with the same retention time as naphthalene and phenanthrene. When acetonitrile was used, the blank was much cleaner and no interferences appeared in the chromatogram.

Table 5 shows the recoveries obtained when different percentages of acetonitrile are used in the analysis of PAHs by online SPE-HPLC. It can be seen that it is necessary to increase the percentage of acetonitrile to increase the recovery of high molecular weight compounds. However, this distorts the peaks of the low molecular weight compounds and so they could not be quantified. This happened to naphthalene, acenaphthene and fluorene when 25% of acetonitrile was used and, for this reason, 15% acetonitrile is the maximum concentration that can be used. However, at this percentage, the recovery value for the high molecular weight compounds is quite low, so the authors recommend that the PAHs should be analysed in two separate runs with 15% acetonitrile and 20% 2-propanol as modifiers, for the low molecular weight compounds (from naphthalene to pyrene) and the high molecular weight compounds (from benzo[a]anthracene to indeno[1,2,3-cd]pyrene). Figure 4 shows a chromatogram of the analysis of 50 mL tap water using acetonitrile as organic solvent for low molecular weight compounds and IPA for the high molecular weight compounds.

Table 5 Recovery values obtained in the analysis of 50 mL of a standard solution of 0.4 µg L⁻¹ using nine SDB discs at several percentages of ACN and IPA

Compounds	Percentage of ACN				Percentages of IPA		
	10%	15%	25%	35%	10%	20%	30%

– Not quantified.

ACN, acetonitrile; IPA; isopropanol.

Using online SPE-HPLC it is possible to detect these compounds at very low ng L⁻¹ levels. Table 6 shows linearity range and limits of detection of PAHs in sea water.

Online coupling of solid-phase extraction to GC or SFC requires an additional step: drying the pre-column before elution with the organic solvent in order to remove the water present when aqueous samples are analysed. An organic solvent added to the samples is also required in order to avoid adsorption of the PAHs. When SPE-GC is used, a small volume of an organic solvent, usually ethyl acetate, is used to pass the retained compounds to the chromatographic column via a loop type or an on-column interface. When SPE-SFC is used, the same mobile phase is used to elute the retained compounds.

Conclusions

PAHs are mainly determined by HPLC fluorescence and detection because of its high sensitivity. To reach the very low levels of concentration required, an extraction concentration technique is necessary. Solid-phase extraction is the preferred technique both for extracting aqueous samples and cleaning up after other extraction techniques.

C₁₈ silica cartridges or discs are the most recommended in online and offline modes.

One of the characteristics of the extraction of PAHs is the need for an organic solvent or a surfactant

Figure 4 LC chromatogram of the analysis of 50 mL tap water using acetonitrile as organic solvent for low molecular weight compounds and isopropanol for the high molecular weight compounds. Analysis of low molecular weight compounds in tap water with addition of a standard solution of 10 ng L⁻¹ (B) and without any addition (A). Analysis of high molecular weight compounds in tap water in the same conditions (C,D). Peak assignment: 1, naphthalene; 2, acenaphthene; 3, fluorene; 4, phenanthrene; 5, anthracene; 6, fluoranthene; 7, pyrene; 8, benzo[*a*]anthracene; 9, chrysene; 10, benzo[*b*]fluoranthene; 11, benzo[*k*]fluoranthene; 12, benzo[*a*]pyrene; 13, dibenz[*a,h*]anthracene; 14, benzo[*ghi*]perylene; 15, indeno[1,2,3-*cd*]pyrene. to be added to the samples, in order to avoid adsorption of these compounds in the system.

The use of solid-phase extraction and HPLC with fluorescence detection enables low levels (at ng L⁻¹ in

water samples) of PAHs to be determined in real samples.

Supercritical Fluid Chromatography

K. D. Bartle, University of Leeds, UK

Copyright © 2000 Academic Press

Introduction

There is tremendous analytical interest in polycyclic aromatic compounds (PAC) because of their carcinogenic properties and their impact on the environment. PAC mixtures can be very complex and extend over a wide range of molecular masses. They mainly originate from the combustion of fossil fuels and are widespread in the environment.

The most commonly used separation techniques for PAC are gas chromatography (GC), high performance liquid chromatography (HPLC) and supercritical fluid chromatography (SFC). GC is often the technique of choice since it works well for low molecular weight and volatile compounds. It is also preferred because the high diffusivity of solutes in gases results in relatively short analysis times. HPLC employs liquids of high solvating power, high densities and high viscosities but is often time-consuming and has much less resolving power than GC.

Separation of PAC by SFC

Although HPLC and GC are commonly used for the analysis of PAC mixtures, SFC has a number of advantages. SCF have diffusivities that are more gas-like, viscosities lower than liquids and densities that are more liquid-like. The resulting mass transfer coefficients lead to a more rapid analysis in SFC than in HPLC. The diffusion coefficients and viscosities of SCF allow GC-like separations on capillary columns but at much lower temperatures because of the high

solvating power of SCF. The approach in SFC involves the use of columns of the packed LC type, packed capillary (micro-packed) and the open tubular (capillary) GC type columns.

SFC on Packed Columns

Packed columns usually of the commercial HPLC variety were used in nearly all the early work in SFC. The length and internal diameter (i.d.) of SFC packed columns are constrained by (a) the larger pressure drops as compared to open tubular columns and (b) high flow rates, making interfacing to GC detectors more difficult. Often, narrow-bore packed columns with a diameter of 1 to 2 mm are used because they can be installed in a capillary SFC instrument and are compatible with many detectors.

Early work on the separation of polycyclic aromatic hydrocarbon (PAH) standards revealed that reduced particle size led to increased resolution, and that analysis times were reduced in comparison with HPLC; it was also shown that PAH elution order could be varied by changing the operating temperature and/or the pressure. Marked changes in retention and selectivity are brought about by the addition of a modifier to the mobile phase. Detailed studies of the retention characteristics of PAH on a wide range of packed columns showed that retention in SFC with CO₂-based mobile phases correlates most closely with reverse phase HPLC. Very rapid analysis (< 6 minutes) of the sixteen Environmental Protection Agency target PAH was demonstrated on a 15 cm long column packed with a specially bonded C₁₈ silica (Figure 1). Efficient separation of PAH can be achieved by coupling columns of different selectivity. Plate numbers up to 220,000 and separation of up to

Figure 1 Supercritical fluid chromatography (SFC) of the EPA/PAH mixture. Chromatographic conditions: 5 mL min⁻¹; CO₂/MeOH mobile phase; gradient of 10% MeOH/min from 1% up to 50% then hold at 50%; pressure gradient of 95 bar min⁻¹ from 80 bar up to 200 bar then hold at 200 bar; temperature 40°C for 3 minutes then gradient of 7°C per minute to 60°C. Detection UV absorbance at 254 nm. Peak identification 1 naphthalene; 2 acenaphthylene; 3 acenaphthene; 4 fluorene; 5 phenanthrene; 6 anthracene; 7 fluoranthene; 8 pyrene; 9 benz[*a*]anthracene; 10 chrysene; 11 benzo[*b*]fluoranthene; 12 benzo[*k*]fluoranthene; 13 benzo[*a*]pyrene; 14 dibenz[*a, h*]anthracene; 15 benzo[*ghi*]perylene; 16 indeno[1,2,3-*cd*]pyrene. Reproduced with permission from Heaton *et al.* (1994).

60 PAH can be achieved by coupling up to seven packed (HPLC) columns together.

SFC on Capillary Columns

Capillary column SFC is often preferred to packed column SFC for separation of PAC mixtures because of better resolution (Figure 2). The price paid, however, is much slower analysis and the use of unmodified CO₂ as mobile phase, in which the higher molecular weight PAC are less soluble.

A variety of mobile phases other than CO₂ have been studied in order to increase the selectivity for a wide range of samples and solutes in work which also indicated that the choice of stationary phase for capillary SFC must take into account the solvating power and the reactivity of the supercritical fluid; the stationary phase must be sufficiently immobilized and must not react with the mobile phase to avoid being washed out of the column by the carrier fluid. Supercritical ammonia has been used because of its high polarity and reasonable critical parameters ($T_c = 132.5^\circ\text{C}$, $P_c = 112.5\text{ atm}$).

A similar range of stationary phases has been used in the capillary SFC of PAC as has been applied in capillary GC: 100% methyl and 5% phenyl siloxanes, and the more selective 5% biphenyl and cyanopropyl siloxanes. Very selective SFC separations have been shown on liquid crystalline phases

(Figure 3). Isomers may be resolved on the basis of the length-to-breadth ratio and planarity of PAH since they are compatible with the ordered 'rod-like' structure of the phase.

Detection in SFC of PAC

Flame-ionization (FID) is the most commonly used detector in capillary SFC of PAC, but the UV absorption detector has most often been applied in packed column work because of the presence of modifiers. Photodiode array detection then allows identification of parent PAH. Nitro PAC have been determined by capillary SFC with the use of the thermionic detector (TID); no modification is necessary and the detector is sensitive and stable during density programming. Low concentrations of sulfur-containing PAC have been detected with the aid of the flame photometric detector in capillary SFC. The photoionization detector uses a high-energy UV lamp to ionize the eluted PAH, and offers high sensitivity with some selectivity over non-aromatic compounds.

Spectroscopic detection has often been used in SFC to allow PAC identification. PAC are weak IR absorbers, but may be identified from the FTIR spectra of compact spots deposited by CO₂ mobile phase elimination at the restrictor exit; PAH isomers may be differentiated by their FTIR spectra, e.g. chrysene from

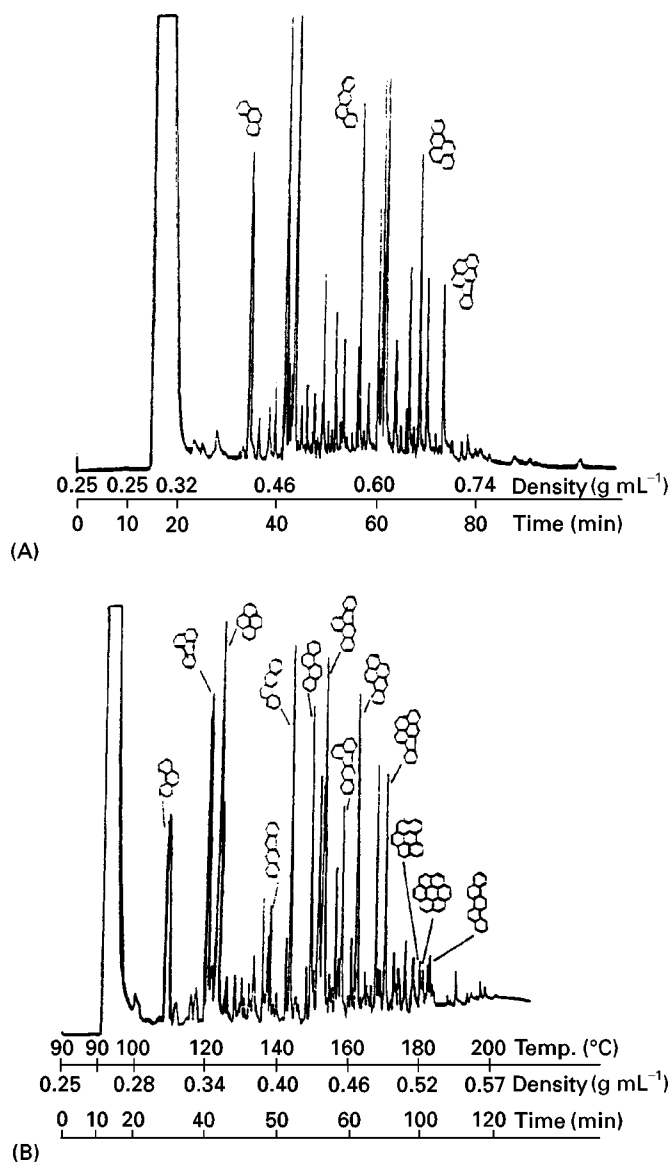

Figure 2 SFC chromatograms of total coal tar polycyclic aromatic hydrocarbons (A) constant temperature 110°C, density program, (B) simultaneous temperature/density program. Chromatographic conditions: (A) constant temperature at 90°C; density ramp rate of 0.007 g mL⁻¹ min⁻¹ up to 0.75 g mL⁻¹; 10-m × 0.50-μm i.d fused silica capillary column coated with biphenyl carboxylate ester liquid crystalline (SB-Smectic); FID at 350°C. Reproduced with permission from Kithinji *et al.* (1990) *Journal of High Resolution Chromatography* 13: 27.

benz[*a*]anthracene. Flow-cell FTIR is less useful in SFC of PAC because of the interference from bands from CO₂ mobile phase. Supercritical xenon is a better solvent than CO₂ for PAH, and does not obscure their FTIR spectra but is extremely expensive.

SFC has been interfaced to mass spectrometry (MS) in a number of analyses of PAC; low flow rates in capillary SFC make it particularly useful. SFC-MS is then employed in the identification of PAC especially from their molecular weights. The fluorescence detector has been used in SFC of PAH mixtures with

pentane mobile phase. Both excitation and emission spectra have been used in high sensitivity analysis of PAH.

Multidimensional Chromatography

PAC mixtures are often too complex for their analysis in a single chromatographic system. Multidimensional chromatography, generating much higher resolution, and improved separation of PAC mixtures, has been demonstrated in coupled SFC-SFC of both

Figure 3 Simultaneous separation of a mixture of 3-, 4- and 5- ring polycyclic aromatic hydrocarbon isomers on biphenyl and smectic columns. Chromatographic conditions: Column 1 – open tubular column coated with a 0.25- μm film of 30% biphenyl-methylpolysiloxane stationary phase (Biphenyl-30); Column 2 – open tubular column coated with a 0.25- μm film of smectic biphenylcarboxylate ester liquid crystalline polysiloxane stationary phase (SB-Smectic-50); CO_2 at 120°C ; pressure program from 150 atm (hold for 10 min) to 450 atm min^{-1} ; FID at 300°C . Reproduced with permission from Raynor *et al.* (1990) *Journal of High Resolution Chromatography* 13:22.

packed column–capillary column and capillary column–capillary column arrangements. The first column can provide chemical class separation, while the second resolves closely related compounds and isomers.

Applications of SFC to PAC Mixtures

SFC is a useful procedure in PAC analysis by providing complementary information to that from GC and HPLC.

Group-type separation by HPLC and open-column chromatograph is unsatisfactory, and SFC methods have proven markedly superior. Packed columns (often silica and silver-salt impregnated silica in tandem) were first used for this application, but certain separations (e.g. saturates from olefins) were often inadequate unless supercritical SF_6 or complex column switching were employed.

Aromatic content of fuels is determined by SFC in an ASTM method on a silica packed column with CO_2 . Separation of aromatic compounds on the basis of ring number has been demonstrated on packed capillary columns, and also by two-dimensional capillary SFC–SFC. FID detection with CO_2 mobile phase allows ready quantitation.

Simulated distillation (SIMDIS) of fuels is often used to replace actual distillation in the determination of boiling point distribution. While GC is often used in SIMDIS, damage to columns and sample degradation resulting from the high temperatures necessary to elute high MW compounds has led to the development of SFC methods in which oven temperatures as low as 150°C are sufficient to elute PAC boiling beyond 750°C because of their greater solubility in supercritical CO_2 mobile phase at densities up to 0.71 g mL^{-1} . A column packed with

C₆ bonded silica was especially useful in correlating SFC retention with boiling point for a variety of PAC types.

PAC from fossil fuel and environmental samples have commonly been analysed by SFC, with an application range beyond that of GC and much improved resolution over HPLC methods. Coal-derived PAH containing as many as twelve rings have been eluted in SFC. Identification and quantitation is straightforward with the aid of FID, UV and MS detectors. Very rapid analysis of environmental mixtures of PAC has been demonstrated on a C₁₈ column with CO₂/methanol mobile phase and simultaneous pressure, temperature and composition programming.

Many nitrogen-containing PAC cannot be analysed by GC because they are thermally labile, and SFC with TID has been especially useful in allowing identification of hydroxynitrofluorenes and nitropyrenequinones.

Polycyclic aromatic hydrocarbons (PAH) originate from organic materials (i.e. oil, gasoline, tobacco, garbage, etc.) due to pyrolysis or incomplete combustion. Several hundred different PAH are known, and traces of them can be found nearly everywhere in our environment. In water PAH occur either in solution or adsorbed on to particulate material. As certain PAH are known to be highly carcinogenic, six easily detectable PAH were specified, in order to be used as indicators for the large group of PAH. The structural formulae of these six compounds are given in Table 1. In 1971 the World Health Organization (WHO) set the maximum acceptable level of the sum of these six PAH in potable waters at 200 ng L⁻¹. This standard was adopted by the European Community, who fixed the maximum admissible concentration for the sum of the six reference substances in drinking water to 0.2 µg L⁻¹, calculated as carbon.

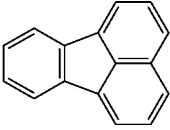

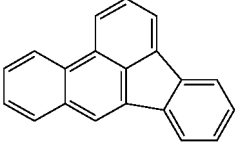

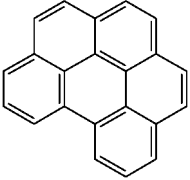

Thin-layer chromatography (TLC) is one analytical method for the determination of these PAH, in addition to other chromatographic techniques. For standard chromatograms, standard solutions containing fluoranthene with five times the level of the other PAH are usually used. This is based on the fact that fluoranthene is present at approximately five times

the level of the other PAH in the majority of water samples. A TLC method using development in two dimensions with two different solvent systems has been known for many years. After separation, the PAH are visualized by irradiation with ultraviolet light, and normally the concentration range of the PAH is visually estimated by comparison with standard chromatograms. In addition to this old semiquantitative TLC method, some modern and more efficient TLC methods have been devised.

The improvement of plate material leading to high performance thin-layer chromatography (HPTLC) allowed the development of efficient procedures for qualitative and quantitative analysis of PAH. A big advantage of the HPTLC methods is the possibility of applying up to 18 samples on to one plate, whereas with the two-dimensional method only one sample could be analysed per plate.

Before the PAH can be separated by TLC, they must be extracted from water samples using, for example, cyclohexane. For a sample volume of 1 L 25 mL of solvent is suitable; larger volumes may be convenient in some cases, e.g. when emulsions form. The solvent extract is concentrated to a small volume and, if necessary, materials interfering in the analysis are removed from the extract using column chromatography with alumina or silica gel. The methods described in the following paragraphs can also be applied to extracts of food, soil, smoke and

other sample material. For some of these samples special, and very time-consuming, clean-up procedures are needed. Therefore TLC is mainly used for the analysis of drinking water.

Thin-Layer Chromatography Method with Development in Two Dimensions

Different adsorbent stationary phases can be used for the separation of PAH. An excellent resolution of the six WHO PAH is obtained on a mixed phase consisting of aluminium oxide G and 40% acetylated cellulose in a 7:3 weight ratio. With these plates fluoranthene can be determined in the range of 10–100 ng per spot and the other PAH in the range of 5–80 ng per spot.

Preparation of the TLC Plates

Plates may be prepared as follows using conventional glass TLC plates and a plate-coating apparatus (the quantities given are sufficient for five plates): 28 g aluminium oxide G and 12 g cellulose 40% acetylated are thoroughly mixed with 5 mL ethanol. Clean glass plates 20 × 20 cm are coated with this mixture at a thickness of 0.25 mm. The coating is air-dried at room temperature for 10–15 min, then activated at 110°C for 30 min. After activation the plates are cooled and stored in a desiccator.

Application of the Sample Extract or Standard Solution

The concentrated extract (0.05–0.1 mL) is spotted in the bottom left corner of the plate, 20 mm from each

edge. Microsyringes or capillaries can be used to apply the sample; the diameter of the spot should be about 4–6 mm. The spotting solvent needs about 2–3 min to evaporate at room temperature.

Standard mixtures of the six PAH are applied in the same manner in order to obtain standard chromatograms for the estimation of the PAH concentration.

Development of the Plates

For the chromatographic separation, tanks which have been allowed to equilibrate with the solvent for at least 15 min are used. The migration distance should be about 18 cm in both directions.

- Solvent system 1: a mixture 9 vol *n*-hexane and 1 vol toluene
- Solvent system 2: a mixture of 4 vol methanol, 4 vol diethyl ether and 1 vol water

After separation in solvent system 1, the plate is removed from the tank and dried at ambient temperature in a fume cupboard for 10–15 min. It is then rotated through 90° anticlockwise from the first direction of development and developed in solvent system 2. Afterwards the plate is again removed from the tank and dried in a fume cupboard at ambient temperature for 10–20 min.

The development times are approximately 30 min for solvent system 1 and 90 min for solvent system 2.

Visual Evaluation of the Chromatograms

The plates are irradiated with 366 nm ultraviolet light to visualize the PAH as a series of fluorescent

Figure 1 Standard PAH chromatogram viewed under UV light with F (1, turquoise), BP (2, violet), BkF (3, violet), IP (4, yellow), BbF (5, turquoise) and BaP (6, violet).

spots. In a dark cabinet plates with standard chromatograms can be viewed simultaneously with a sample chromatogram to estimate the concentration visually. A typical standard chromatogram is given in **Figure 1**. A chromatogram of a river water sample is shown in **Figure 2**.

Quantification of the Spots using a Scanning Fluorimeter

It is also possible to evaluate the chromatograms using a scanning fluorimeter, but this procedure is very time-consuming and therefore in most cases only semiquantitative evaluation by visual estimation is used.

Table 2 Suitable excitation and emission wavelengths

Compound	Excitation wavelength (nm)	Emission wavelength (nm)
Fluoranthene	365	462
Benzo(b)fluoranthene	302	452
Benzo(k)fluoranthene	302	431
Benzo(a)pyrene	297	405 or 430
Benzo(ghi)perylene	302	419 or 407
Indeno(1,2,3-cd)pyrene	300	500

For the scanning method, first the coordinates defining each spot are recorded using a standard plate. The instrument settings (slit height and width, wavelengths, etc.) required to achieve good curves must be determined individually for the available equipment, because these settings will vary with the type of instrument. For guidance, suitable excitation and emission wavelengths are given in **Table 2**.

The standard and the sample plates are scanned using the same instrument settings. For each spot on the plates the area of the peak is measured. The mass of each individual PAH in the sample can then be calculated by comparison with the standard.

Determination of PAH by HPTLC with Fluorescence Detection

The two methods described below are applicable to the determination of the six selected PAH in drinking

Figure 2 River water chromatogram viewed under UV light with F (1, turquoise), BP (2, violet), BkF (3, violet), IP (4, yellow), BbF (5, turquoise) and BaP (6, violet).

water, ground waters and moderately polluted surface waters. For other samples, containing a lot of interfering substances, specially developed clean-up procedures are necessary.

The first method uses HPTLC RP-18 plates and is a screening method for semiquantitative determination. It can be used to screen for samples with PAH concentrations near or above the limiting value, which then have to be analysed quantitatively.

For the quantitative method, using caffeine-impregnated HPTLC silica gel plates, the chromatograms are evaluated by *in situ* fluorescence measurement at constant or differing wavelength combinations. This method has a working range of 40–240 ng L⁻¹ for the sum of the six PAH.

PAH are extracted from the water sample by liquid-liquid extraction as described above. The extract is evaporated to dryness and the residue taken up in a small defined volume of solvent. An aliquot of this extract is applied on to the HPTLC plate. A more detailed description of the methods is given below.

HPTLC Method with RP-18 Plates

Plate Material

HPTLC-pre-coated RP-18 plates, preferably with fluorescence indicator, are used. Plates with concentrating zones may also be used. RP-18 materials with different degree of coverage (carbon loading) are commercially available and, depending on this, different mobile phases have to be used.

Application of Sample Extracts and Standard Solutions

Several samples may be analysed simultaneously on one HPTLC plate, together with two or more reference solutions of different concentrations. For screening purposes it is also possible to apply sample extracts and reference solutions on both ends of the HPTLC plate, provided the plate is developed in a horizontal development chamber.

Aliquots, e.g. 25%, of the total sample extracts (40–120 µL) are applied either by means of an automated volume-dosing device or by hand as bands or spots. For the application of spots HPTLC RP-18 plates with a concentrating zone are preferred and the volumes should not be more than 10 µL. If using band application, the bands should have a length of 7 mm and the intervals should be 3 mm. For band application the extract should not be too concentrated, and it is advantageous to apply higher volumes, e.g. 30 µL.

Development of the Plates

The development is performed in a development chamber for low consumption of mobile phase, suitable for trace analysis.

Depending on the carbon loading, one of the following mobile phases is used:

- a mixture of acetonitrile, 2-propanol and methanol (1 + 2 + 1) for high carbon loading C₁₈ material
- a mixture of acetonitrile, water and methanol (10 + 2 + 10) for low carbon loading C₁₈ material

The chromatogram is developed at room temperature either vertically in a trough chamber or horizontally in a horizontal development chamber, without chamber saturation. Using a trough chamber, the run time for a migration distance of 6.5 cm is about 20 min. In a horizontal development chamber, the run time for a migration distance of 6 cm is about 20 min, and for 4.5 cm about 15 min.

After development the plate is dried for 2 min in a stream of air at ambient temperature.

Visual Evaluation of the Chromatograms

If the dried plate is viewed under an ultraviolet lamp at 366 nm only three to four fluorescing zones can be recognized. Figure 3 shows two examples: first, a chromatogram of the six PAH on a plate with high carbon load C₁₈ material, with a concentrating zone,

Figure 3 Chromatogram of the six PAH on HPTLC RP-18 plates. (A) high carbon load C₁₈ material, plate with concentrating zone; (B) low carbon load C₁₈ material.

Figure 4 Fluorescence scan of a chromatogram track with 2 ng per spot of BP, IP, BaP, BbF, BkF and 10 ng per spot of F. The separation from the start to the front is IP (1), BP (2), BaP and BkF (3), BbF (4) and F (5).

and second, a chromatogram of the six PAH on a plate with low carbon load C_{18} material.

This separation is sufficient to evaluate the sample chromatograms visually by comparison with standard chromatograms. The individual PAH can be identified by colour, R_F value, and position relative to the reference chromatogram. The colours of the PAH are: F = light blue, BkF = dark blue, BbF = blue, BaP = violet, IP = light yellow and BP = violet. The concentration of the PAH in the sample extracts can be estimated by the fluorescence intensity of the zones. If, as in most drinking and ground waters, the fluorescence intensity is not stronger than the fluorescence of a corresponding standard, the PAH concentration lies below the limiting value, and therefore quantitative measurement is not necessary.

Influence of Temperature

Working at lower temperatures leads to better separation. The six PAH can be separated at -20°C into five fractions. Figure 4 shows the fluorescence scan after chromatographic development on a high carbon load C_{18} material. The separation is still not satisfactory as BaP and BkF are not separated. Due to this, the described separation technique is not suitable for quantitative analysis of the individual compounds.

HPTLC Method with Caffeine-impregnated Silica Gel Plates

The ability of PAH to form charge transfer complexes can be successfully employed when applied to silica gel thin layers impregnated with different electron acceptors, such as caffeine. In the following paragraphs charge transfer chromatography on caffeine-impregnated HPTLC silica gel plates is described. The chromatographic separation at room temperature is an alternative method to the screening method on HPTLC RP-18 plates. If the development is performed at -20°C , the six PAH can be easily separated into six fractions and the chromatograms can be evaluated quantitatively.

Plate Material

Caffeine-impregnated HPTLC silica gel 60 plates are commercially available, but the impregnation can also be carried out in the laboratory.

For caffeine impregnation HPTLC silica gel 60 plates are dipped for 4 s into a solution containing 4 g caffeine in 96 g dichloromethane and then dried at 110°C for 30 min. Prior to use, the plates should be cleaned by running a blank chromatogram to the upper edge, using dichloromethane. This pre-washing step is especially recommended if quantitative determination is intended. Afterwards the plates need to be reactivated by heating at 110°C for 30 min. The activated plates should be stored in a desiccator until use.

Application of the Sample Extracts and Standard Solutions

Aliquots of sample extracts and standard solutions are applied on to the same plate, preferably as bands, using an automated volume-dosing device.

For screening purposes, extracts and standard solutions are applied as bands or spots on both ends of the HPTLC plate, provided the plate is developed in a horizontal development chamber.

For quantitative analysis only band application is recommended. The bands should have a length of 7 mm and the intervals should be 3 mm. The applied volumes should be between 10 and 30 μL .

Development of the Plates at Room Temperature

After application of the samples, the plate is preconditioned for 30 min over water. Then the chromatogram is developed vertically or horizontally in a development chamber without chamber saturation, using a mixture of diisopropyl ether and *n*-hexane (4 + 1) as mobile phase. Using a trough chamber, the run time for a migration distance of 6.5 cm is about 25 min; in a horizontal development chamber, the run time for a migration distance of 6.5 cm is about 15 min, and for 4.5 cm about 10 min. After development the plate is dried for 2 min in a stream of air at ambient temperature. Then, in order to stabilize the fluorescence intensity of the chromatogram zones for more than 1 h, the plate is dipped into a solution of liquid paraffin-*n*-hexane (1 + 2) for 2 s, then dried again for 2 min. This not only leads to stabilization but in addition the fluorescence intensity is doubled for F, BkF, BbF and IP, and enhanced by a factor of 5 for BaP and BP.

Visual Evaluation of the Chromatograms

If the dried plate is viewed under an ultraviolet lamp at 366 nm, five fluorescing zones can be recognized (Figure 5A). The individual PAH can be identified by colour, R_F value and relative position to the reference chromatogram. The concentration of the PAH in the

Figure 5 (A) Chromatogram of the six PAH on a caffeine-impregnated HPTLC silica gel plate. Development at room temperature. (B) Fluorescence scan of a chromatogram track with 2 ng per spot BP (1), IP (2), BaP (3), BbF (4) and BkF (5) and 10 ng per spot of F (6). Development at room temperature.

sample extracts can be estimated by the fluorescence intensity of the zones. The fluorescence scan of the chromatogram (Figure 5B) shows that there is no baseline separation between BaP and BbF. Therefore a quantitative evaluation of the chromatograms, developed at room temperature, would not yield reliable results for these substances.

Development of the Plates at -20°C

After sample application, the plate has to be precooled in a freezer cabinet at -20°C for 20 min. Then the chromatogram is developed vertically in a trough chamber without chamber saturation at -20°C with dichloromethane as mobile phase. The chamber has to be kept, for equilibration, at -20°C for at least 60 min before the analysis. The run time for a migration distance of 6.5 cm is about 20 min. Development in a horizontal development chamber does not give reproducible results.

After development the plate is dried for 2 min in a stream of air at ambient temperature. Then, in order to stabilize and increase the fluorescence intensity of the chromatogram zones, the plate is dipped, as described above, into a solution of liquid paraffin-*n*-hexane.

Fluorescence Densitometric Evaluation

Using the separation procedure at -20°C described above, the six PAH can be completely separated. Therefore this procedure is well suited for quantitative determination.

The chromatograms can be evaluated by measuring either the peak height or peak area using a scanner at an excitation wavelength of 366 nm and a fluorescence wavelength of 400 nm (edge filter). Standard chromatograms are evaluated to calculate a calibration function. The fluorescence intensity of the chromatogram zones is linearly related to the amount of PAH applied, up to 12 ng per spot for fluoranthene and up to 2.4 ng per spot for the other five PAH. The precision of the calibration functions is excellent (coefficients of variation between 1.7% and 3.8%).

If applying spots, the slit of the scanner should be broader than the largest zone of the chromatogram in the *x*-direction. If applying bands, the recommended slit width in the *x* direction is 1/2 to 2/3 of the band length. In the *y* direction, the slit should not be smaller than 0.3 mm.

Figure 6A shows the position of the six PAH on the caffeine-impregnated HPTLC silica gel plate. The fluorescence chromatogram (Figure 6B) demonstrates that the described procedure yields nearly baseline separation.

Figure 6 (A) Chromatogram of the six PAH on caffeine-impregnated silica gel plates, developed at -20°C ; (B) Fluorescence chromatogram of a track with 2 ng per spot BP (1), IP (2), BaP (3), BbF (4) and BkF (5) and 10 ng per spot of F (6); development at -20°C .

Figure 7 shows the chromatogram of a ground water sample, in which all six PAH were found, plus one unknown fluorescing substance. This was an ideal sample, but other fluorescing substances may interfere with the determination of the PAH. In such cases the PAH can be selectively detected, using different excitation and emission wavelengths.

Figure 7 Fluorescence scan of a ground water sample with BP (1), IP (2), BaP (3), BbF (4), BkF (5), F (6) and an unknown substance (7).

Spectroscopic Identification

As the six PAH show different optical properties it is possible to detect them selectively. With HPTLC, which is characterized by offline detection, it is easy to repeat the scanning procedure several times using different easily selectable fluorimetric conditions within a short time period.

For example Figure 8 shows the evaluation of the same chromatogram at different excitation wavelengths and emission filters. By spectroscopic selection it is possible to guarantee the correctness of qualitative and quantitative results.

Conclusion

TLC is an efficient and versatile analytical method. The costs per sample are low and, because many samples can be analysed in one development step, the time to achieve results for a series of samples is comparably short. Although TLC has many advantages, this method is not often used for the analysis of PAH; the equipment for quantitative HPTLC is not widespread in water laboratories and only the screening method to control the observance of the limiting value for drinking water has found greater acceptance. Many laboratories prefer high performance liquid chromatography or gas chromatography for

Figure 8 Fluorescence scan of the same chromatogram track. Selective detection using different excitation (λ_{exc}) and fluorescence (λ_{fl}) wavelengths: (A) $\lambda_{\text{exc}} = 365 \text{ nm}$; $\lambda_{\text{fl}} = 436 \text{ nm}$; (B) $\lambda_{\text{exc}} = 436 \text{ nm}$; $\lambda_{\text{fl}} = 578 \text{ nm}$; (C) $\lambda_{\text{exc}} = 405 \text{ nm}$; $\lambda_{\text{fl}} = 436 \text{ nm}$; (D) $\lambda_{\text{exc}} = 334 \text{ nm}$; $\lambda_{\text{fl}} = 436 \text{ nm}$.

the quantitative determination of PAH, because the separation efficiency of these methods is better and they can be automated. Therefore further development in the field of PAH determination with TLC cannot be expected, although modern HPTLC offers a lot of possibilities.

Introduction

Before chromatography became an efficient tool for polymer fractionation, classic extraction procedures played a dominant role. These techniques comprise, e.g., dissolution and precipitation, depending on the solvent-non-solvent ratio and M_r , extraction of native polymer or polymer adsorbed onto a solid support with organic solvents of increasing dissolution capability, and partition between two immiscible liquids. In contrast, Baker-Williams and temperature rising elution fractionation (TREF), also used in polymer chemistry, are chromatographic techniques. Although separation of polymers by means of various classic extraction procedures are still in use, chromatographic characterization now plays the dominant role and affords an optimum degree of structural information. In this respect, polyethers of the polyethylene glycol (PEG), polypropylene glycol (PPG) and polybutylene glycol (PBG) family, all extensively used in different fields of chemistry and engineering, have been selected as model compounds for separation of polymers because they differ widely in chemical properties and polarity, ranging from hydrophilic (PEGs) to hydrophobic (PBGs) in either native form or mono-(di-)O-alkyl(arylalkyl) (Figure 1A–C) and amino-terminal derivatives (Figure 1B). For this reason, they comprise a group of polymers accessible to a broad range of chromatographic separation techniques including high performance liquid chromatography (HPLC), size-exclusion chromatography (SEC), thin-layer chromatography (TLC), supercritical fluid chromatography

(SFC) and capillary zone electrophoresis (CZE). Gas chromatography (GC) only provides separation of the low-molecular-weight (M_r) members of polyethers with upper limits of M_r of approximately 600. TLC and SFC are of minor importance and are not considered. Although extensively used for determination of M_r values, SEC is also excluded because it exhibits only moderate resolution and does not permit differentiation of the individual types of polyether on the basis of the underlying chemistry.

This survey gives a short overview of the current state of HPLC technology of polyethers and deriva-

tives. For more detailed information on liquid chromatography of this class of substances the reader is referred to recently published review articles (see Further Reading).

Special Features of Chromatographic Separation of Polymer Systems

Chromatographic behaviour of synthetic polymers substantially differs from that of low-molecular-weight analytes for a variety of reasons: (i) small diffusion coefficients of macromolecules in solution, (ii) the size of the macromolecules often being of the same order of magnitude as the pore diameter of the stationary phase, (iii) retention of polymers via trains of numerous repeat units, (iv) flexibility of the polymer chains enabling conformational changes, and (v) limited solubility. Synthetic polymers are usually composed of a large number of identical structural units, which dependent on the experimental conditions, give rise to more or less broad M_r distribution, ranging from some hundreds to millions. The situation is still more complicated when statistical, random and block copolymers are formed. Isocratic HPLC, typically applied for low M_r analytes, is not suited for exhaustive separation of individual oligomers, because of the great number of molecules often differing greatly in M_r . Separation of polymers built up from different chemical units (e.g., copolymers and/or polymers containing different end groups, such as, e.g., non-ionic surfactants) should ideally be effected according to either degree of polymerization expressed by the number of repeat units n and thus, M_r weight distribution, or chemical composition (CCD) and functionality type distribution (FTD). However, unfortunately, only in rare cases are both aims achievable within a single chromatographic run and therefore, so-called two-dimensional chromatography is required.

Furthermore, in a much more pronounced manner than for low-molecular-weight analytes, conformational effects must be considered appropriately taking into account distinct structure-dependent intramolecular interactions invoked by both nonpolar (e.g., hydrophobic = van der Waals) and polar (e.g., hydrogen bonding, dipole–dipole, ionic, etc.) interactions. All these effects are responsible for the often

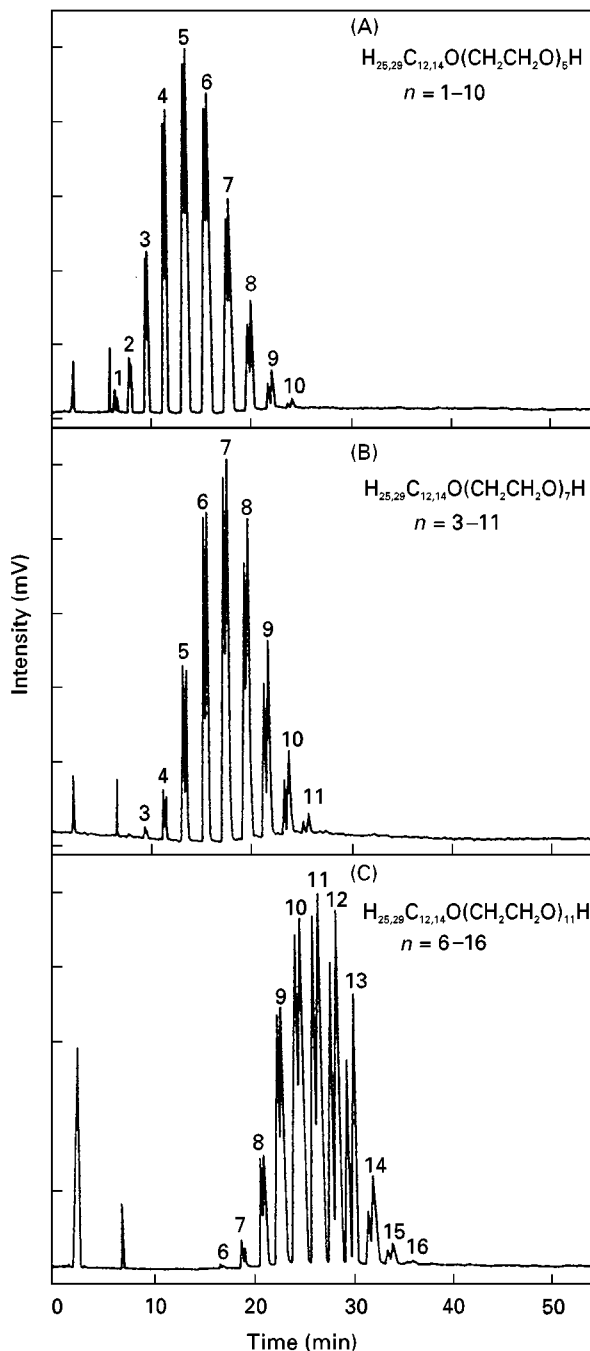

Figure 3 HPLC analysis of linear alkylethoxyalcohol oligomers: (A) AE5; (B) AE7; (C) AE11. (Reproduced from Bear GR (1988) *Journal of Chromatography* 459: 91–107, with permission from Elsevier Science.)

unexpected chromatographic properties more or less substantially deviating from the analyte's intrinsic hydrophobicity based on calculation of hydrophobic increments. This behaviour takes into account the phenomenon of multiple attachment of the polymer chain, which means that adsorption onto the stationary phase surface is not effected by participation of the whole macromolecule but attributable to alternating trains of repeat units, whereas a substantial part of the molecule still extends into the surrounding mobile phase. Moreover, the flexibility of the chains easily allows conformational changes, which are further influenced by the gradual change in mobile phase composition during gradient chromatography.

High Performance Liquid Chromatography of Polyethers

Normal-Phase Liquid Chromatography (NP-HPLC)

NP-HPLC is defined as separation on polar stationary phases using pure organic eluents of increasing polarity. For this reason, either bare silica gel or so-called bonded-phase materials, such as 3-cyanopropyl- (CN), 3-aminopropyl- (NH_2) as well as 2,3-dihydroxypropyl (Diol) silica gel are used as solid supports for the separation of fatty alcohol and fatty acid polyethoxylates, the lower M_r members of native PEG and the corresponding octyl- and nonylphenol derivatives. In general, separation occurs with respect to the number of ethoxymers, although side-chain isomerism as well as differences in the length of the alkyl substituent is also observed in some cases yielding substantial splitting of the oligomer peaks. In contrast, polypropylene (PPG) and polybutylene glycols (PBG), possessing a substantially more hydrophobic polymer backbone, are better separated by

Figure 5 LC/MS chromatogram obtained by injecting the composite working standard solution containing NPEOs and alkylethoxylates (AEOs). The analytes in this synthetic mixture are, in order of elution: 1, NPEOs; 2, C-12 EOs; 3, C-13 EOs; 4, C-14 EOs; 5, C-15 EOs; 6, C-16 EOs; and 7, C-18 EOs. IS (internal standard), C-10 EO₆. (Reproduced from Crescenzi C, Di Corcia A and Samperi R (1995) *Analytical Chemistry* 67: 1797–1804.)

reversed-phase HPLC (RP-HPLC). Whereas combinations of pure organic solvents often containing small amounts of water to accelerate the adsorption-desorption equilibrium are used on bare silica, the NH_2 , CN and Diol materials are also run under typical RP-HPLC conditions with aqueous organic eluents. Although native silica gel is still used for PEG derivatives, it is being replaced more and more by

Figure 6 Separation of ethoxylated hexadecanol C16EO (average ethoxylation degree = 10) on reversed phases (stationary phase: Nucleosil 120-3 C18 (250 × 4); mobile phase: A- H_2O , B- CH_3CN , 1 mL min⁻¹. Gradient programme: 46 → 55% B/20 min, 55 → 76% B/30 min, 76 → 90% B/15 min; ELSD-50 mm N₂, 110°C). (Reproduced from Miszkiewicz W and Szymanowski J (1996) *CRC Critical Reviews in Analytical Chemistry* 25: 203–246.)

Figure 7 HPLC analysis of PEG with an average molecular weight of 2000 daltons carried out on two ODS columns at 60°C and with a detector sensitivity of 0.2 a.u.f.s. (Reproduced from Escott REA and Mortimer N (1991) *Journal of Chromatography* 553: 423–432, with permission from Elsevier Science.)

CN, NH₂ and Diol matrices, which behave as deactivated silica and thus allow a better fine-tuning of the chromatographic conditions. In addition, PEGs with $M_r > 2000$ are irreversibly retained on bare silica gel matrices and thus should be separated by RP-HPLC. It should be emphasized that the bonded-phase materials are not as sensitive towards traces of water in organic solvents compared with silica gel and retention times and peak shapes exhibit excellent reproducibility making them suitable for long-term application without marked loss of chromatographic performance.

Although isocratic NP-HPLC yields satisfactory resolution of PEGs with lower degree of oligomeriza-

tion, the higher oligomers are often truncated and merge more and more with the baseline. This drawback can easily be overcome by the solvent gradient technique, which is the predominant method for separation of polymers. Usually, chromatography starts with a mobile phase of low polarity, such as, e.g., n-hexane, n-heptane, isooctane, cyclohexane, etc., and methanol, ethanol, acetonitrile, 2-propanol, tetrahydrofuran (THF), dioxane, etc., are used as the polar modifiers. Due to insufficient miscibility when using methanol and acetonitrile in combination with alkanes, a third component affecting solvent compatibility is required and THF, dichloromethane and chloroform have been successfully applied. In contrast, ethanol and 2-propanol being more lipophilic compared to methanol and acetonitrile, dissolve in aliphatic and cycloaliphatic solvents at any volume ratio. In particular when using the most polar silica gel, elution is often started with a significant percentage of solvents with intermediate polarity like dichloromethane, chloroform or diethyl ether instead of pure alkane and thus, no additional compatibility modifier is necessary. Nevertheless, a third eluent is often used for chromatographic fine-tuning.

Excellent oligomer resolution of octylphenyl-(OPEO), nonylphenyl-(NPEO) and alkyl-ethoxylates is achieved on bare silica gel (Figure 2), CN, NH₂ (Figure 3), *p*-nitrophenyl-bonded silica (Figure 4) and Diol matrices.

Sometimes peak-splitting of the signals of the individual NPEO oligomers occurs, revealing structural heterogeneity within the nonyl side chain, which is

Figure 8 Chromatograms of 3,5-dinitrobenzoyl derivatives of PEGs by HPLC. Conditions: column. 5 μ m Spherisorb NH₂ (250 \times 4.6 mm I.D.); detection, UV at 276 nm (A) PEG 1000, (B) PEG 2000. not observed in OPEOs. In the same way separation according to the number of ethoxymers (EO) units as well as the chemical composition of the fatty alcohol chain of nonionic surfactants (NIS) is achieved on an NH_2 stationary phase (Figure 3). Nevertheless, in most cases information with respect to both ethoxymers distribution and chemical composition of the alkyl substituent is unsatisfactory and thus RP-HPLC is required for differentiation of the alkyl end groups. Due to the increasing interactive surface of the PEG derivatives with increasing number n of repeat units, retention time of each oligomer increases with M_r , whereas in contrast, the lipophilic end group plays an only marginal role.

In the case of OPEOs and NPEOs bearing an aromatic moiety, signal monitoring is easily accomplished by both UV and fluorescence detection (FD), whereas evaporative light scattering detection (ELSD) is preferred for the alkylpolyethoxylates (Figure 3).

However, in gradient elution with varying concentration of a modifier more or less absorbing in the lower UV range, such as, e.g., ethyl acetate, THF, etc., it is advisable to use wavelengths ≥ 250 nm to keep the baseline drift as low as possible. Polyether derivatives lacking a chromophore, such as fatty alcohol or fatty acid polyethoxylates, are amenable to UV detection after conversion to their benzoyl, 3,5-dinitrobenzoyl and phenylurethane derivatives, which in general, give high yields. Furthermore, for extremely sensitive measurement, the hydroxy functions of the polyether samples can be reacted with fluorophores providing high quantum yields, like fluorenylmethoxycarbonyl chloride, 1-naphthylisocyanate, 1(2)-naphthoyl chloride, carbazol-9-carbonyl chloride, 1(9)-anthrolycyanide, etc. Whereas derivatizations with isocyanates run uncatalysed at about 60°C within 1–2 h, the acyl chlorides require base catalysis (e.g., pyridine, triethylamine,

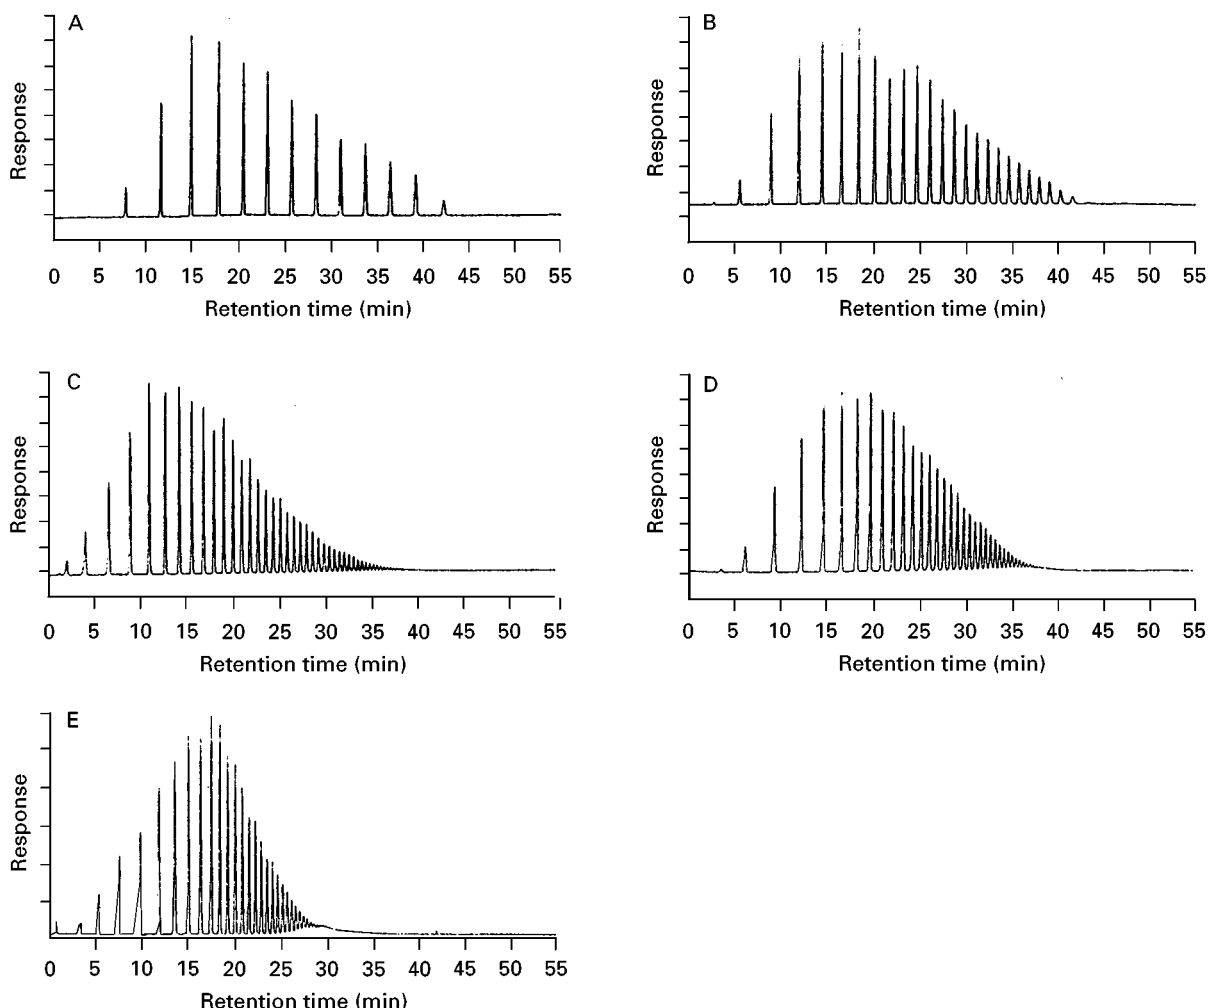

Figure 10 Chromatograms with PBG-1000 and acetonitrile as organic solvent. (A) C_{18} ; (B) C_8 ; (C) C_4 ; (D) C_{phenyl} ; (E) C_1 . (Reproduced from Rissler K, Künzi H-P and Grether H-J (1993) *Journal of Chromatography* 635: 89–101, with permission from Elsevier Science.)

methylimidazole, etc.). In the latter cases either heating for about 0.5–1 h or working at room temperature for about 0.5–2 h generally affords good yields.

Reversed-Phase Liquid Chromatography (RP-HPLC)

RP-HPLC is effected on hydrophobic stationary phases using eluents of decreasing polarity. In general, it is the method of choice for separation of PEG-based nonionic surfactants (NIS) with respect to the chemical structure of the hydrophobic end groups without separation according to the degree of ethoxylation (Figure 5) and also PEGs, PPGs and PBGs. In most applications octadecasilyl silica gel (C_{18}) and/or octylsilyl silica gel (C_8) stationary phases with binary gradients of acetonitrile (methanol)–water are used.

Separation of alkylpolyethoxylates according to the number of ethoxylate units with an acetonitrile

–water gradient on a C_{18} column has also been reported (Figure 6) and retention increases with decreasing number of ethoxymers. Surprisingly, the elution order of oligoethylene glycol phenyl (octylphenyl) ethers is reversed in mobile phases of methanol and water.

Although being significantly less hydrophobic than their corresponding NIS counterparts, satisfactory separation of PEGs is achieved for the species up to $M_r \approx 2000$ using a C_{18} column, whereas in general, PEGs with $M_r \geq 2000$ merge more and more into a common signal envelope. Figure 7 reveals separation of PEG 2000 by use of two C_{18} columns in series.

Despite the fact that separation of PEGs according to the degree of ethoxylation decreases substantially at $M_r > 2000$, PEGs widely differing in M_r ranging from some hundreds to some hundred thousands can be efficiently separated from each

Figure 11 RP-HPLC of Jeffamine D 400™ derivatized with 2,4-dinitrofluorobenzene on a Nucleosil 5C18 column (125 × 4.6 mm; 5 μm) with a gradient from water to 65% acetonitrile–10% THF at 25 min, 80% acetonitrile–20% THF at 40 min, 80% acetonitrile–20% THF for 10 min followed by a drop to the starting conditions and re-equilibration for 14 min at a flow rate 1.5 mL min⁻¹; detection wavelength 355 nm. (Reproduced from Rissler K (1998) unpublished results.)

other as single peaks using binary acetonitrile (methanol)–water gradients and C₁₈ or C₈ stationary phases. In contrast, bonded phases, such as CN and Diol materials, run under RP-HPLC conditions, are less suited for efficient separations of PEGs with $M_r \leq 2000$ into their oligomers. The exception is an NH₂ matrix providing excellent separation of PEGs up to M_r of about 2000 as their 3,5-dinitrobenzoyl derivatives with a binary gradient of acetonitrile and water (Figure 8).

As a consequence of the substantially better interaction of their more hydrophobic backbones with nonpolar stationary phases, PPGs (Figure 9) and PBGs (Figure 10) are much better resolved into individual oligomers and often baseline separation is achieved.

PPGs up to $M_r \approx 2000$ can be sufficiently separated with binary acetonitrile–water gradients, whereas the higher M_r oligomers elute as more or less broad but unresolved signals. At $M_r > 2000$ it becomes more and more difficult to achieve complete elution of either native PPGs or their amino-terminal derivatives from a highly hydrophobic C₁₈ matrix with binary gradients of acetonitrile and water. However, when acetonitrile is replaced by methanol, complete elution of PPGs with higher M_r is accomplished, but the oligomers merge into an unresolved signal envelope. This is attributed to a better solvation of the polyether backbone by methanol compared with acetonitrile due to hydrogen bonding between the ether oxygens and the hydroxy function of methanol and therefore, interactions with the hydrophobic stationary phase are efficiently counterbalanced. The obvious ‘sticking effect’ of high M_r PPG samples onto

a C₁₈ column can also be overcome by stationary phases with lower carbon content, such as, e.g., C₈ and C₄ matrices with acetonitrile as well as methanol as the organic modifier, both showing comparable efficiency. Alternatively, THF can be used as a ‘solubility enhancer’ in combination with acetonitrile for separation of either PPGs or PBGs on C₁₈ stationary phases.

Conversion of the native PPG amines (Figure 1b) into their acetamide or 2,4-dinitrofluorobenzene (DNFB) derivatives (Figure 11) prior to chromatography, which is readily achieved with pyridine–acetic acid anhydride (1 : 1, v/v) or DNFB, respectively, is required to avoid interactions with residual silanols. Alternatively, the unmodified amines can also be separated with trifluoroacetic acid (TFA) as a mobile

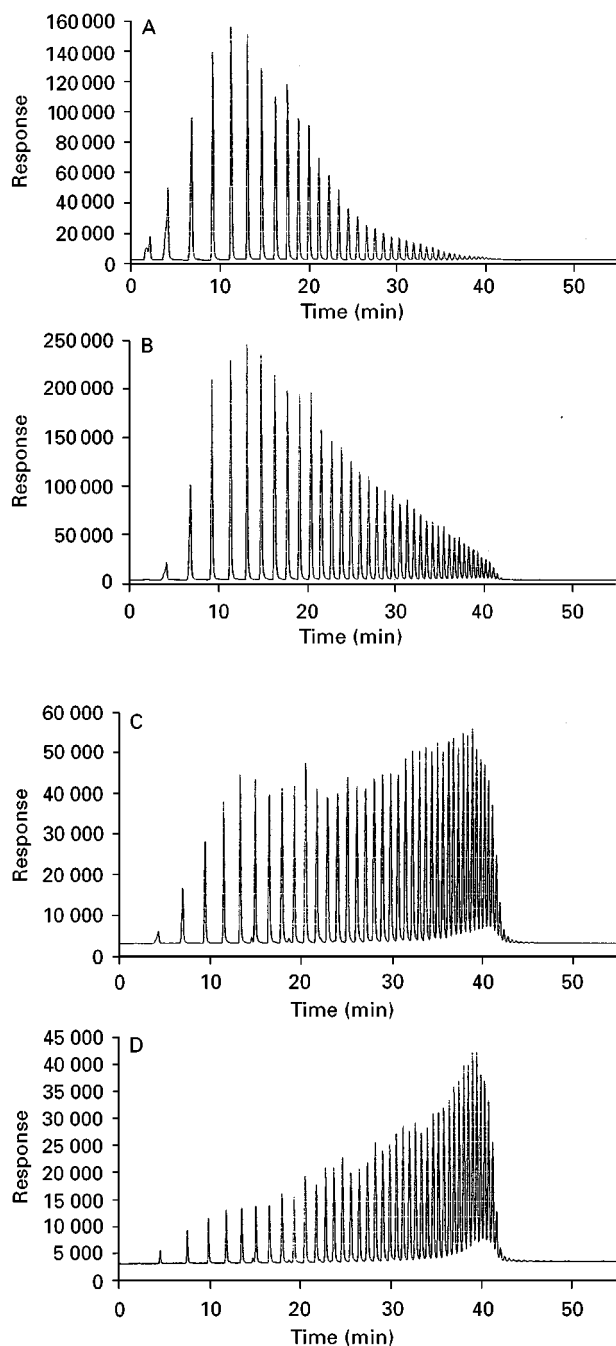

Figure 13 Chromatograms of (A) PBG 650, (B) PBG 1000, (C) PBG 2000 (D) PBG 3000 on a C_4 column and acetonitrile as organic modifier. (Reproduced from Rissler K and Fuchslueger U (1994) *Journal of Liquid Chromatography* 17: 2791–2808.)

phase additive for suppression of silanophilic interactions, but signal resolution is lower compared with the corresponding acetamides and DNFB derivatives.

PBGs exhibit still more pronounced solute–matrix interactions and so PBG 650 (average M_r 650) does not completely elute from a C_{18} matrix with a binary gradient of acetonitrile and water. In contrast, com-

plete elution as well as excellent peak resolution is achieved on a C_{18} column with methanol as the organic modifier, whereas under these conditions, substantial amounts of PBG 1000 still remain on the stationary phase. A further change of organic modifier to ethanol or isopropanol affords complete elution of PPG 1000 (Figure 12), PBG 2000 and PBG 3000, but only the low-to-medium M_r oligomers are sufficiently separated, whereas the higher M_r sample constituents merge into a broad and unresolved signal. Presumably the same solvation effect as postulated for the PPGs also holds true.

Either excellent separation or complete elution is achieved for PBG 650, PBG 1000, PBG 2000 and PBG 3000 on a C_4 matrix with a binary gradient of acetonitrile and water and up to about 60 oligomers are observed (Figure 13). Although a column with markedly lower hydrophobicity compared with C_{18} and C_8 stationary phases is used, interactions of the substantially more hydrophobic PBG samples compared with PPGs are sufficient to give good resolution.

Underivatized PEGs, PPGs and PBGs are eluted in the range of increasing M_r , due to their continuously increasing interactive surface, whereas in the case of PEGs, the converse is true for the corresponding alkyl- and/or arylalkyl-substituted derivatives as a consequence of the dominant role of the lipophilic substituent on solute–stationary phase interactions.

Both signal monitoring by UV and ELSD can be applied and in particular ELSD is the method of choice for the native polyethers when sensitivity is not crucial, because it is at least one order of magnitude less sensitive than UV detection. Therefore, measurement of low amounts of polyethers requires derivatization with a chromophor or fluorophor. However, reaction with aromatic moieties has a dramatic influence on signal resolution of PEGs, which almost completely vanishes, whereas in contrast, PPG (Figure 14) and PBG (Figure 15) oligomers are still well resolved after conversion to their 3,5-dinitrobenzoyl derivatives. PPG amines having been reacted to the corresponding acetamides (DNFB derivatives) can be measured by either UV detection at 210 (355) nm or ELSD.

Unlike a UV detector, where concentration-dependent responses are measured and for this reason, calculation of response factors for the different oligomers is required, ELSD is a typical mass detection system like a refractive index detector. As a consequence, the signal intensities reflect the true mass distribution of oligomers. Moreover, ELSD offers an advantage over UV detection because it allows the use of solvents strongly absorbing in the usual UV range, such as, e.g., acetone and methylethylketone, and

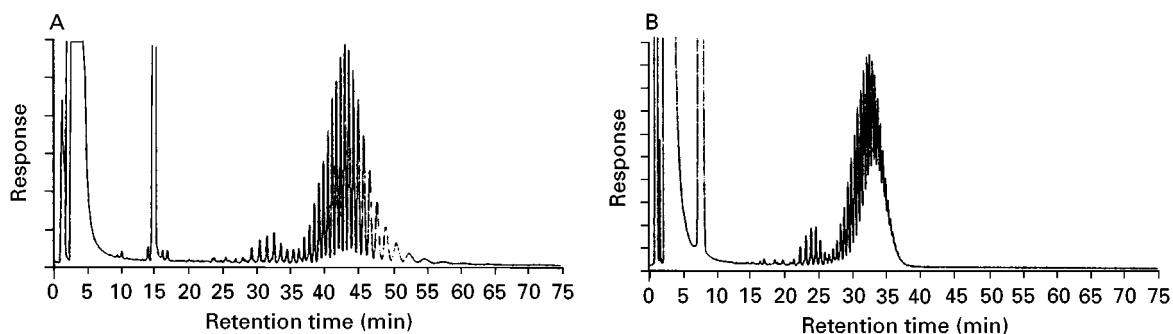

Figure 14 Chromatograms with PPG-1200 after derivatization with DNBCl and acetonitrile as organic solvent. (A) C_{18} ; (B) C_8 . (Reproduced from Rissler K, Künzi H-P and Grether H-J (1993) *Journal of Chromatography* 635: 89–101, with permission from Elsevier Science.)

furthermore, no baseline drift is observed with gradient elution.

Dual detection offers a further powerful tool in polymer separation and measurement of both UV and ELSD responses allow differentiation of, e.g. polyethoxylates containing either aromatic or aliphatic end groups.

During the past few years HPLC-mass spectrometry (LC-MS) has gained increased interest providing exact structural information and opening an additional dimension for polymer characterization. In contrast, matrix-assisted laser desorption ionization time-of-flight mass spectroscopy (MALDI-TOF/MS) is still used off-line and is excellently suited for M_r and end group determination.

'Pseudo Reversed-Phase' Liquid Chromatography (pseudo RP-HPLC)

In contrast to their use in classical NP-HPLC with pure organic solvents of increasing polarity, bare silica gel stationary phases can also be operated with aqueous organic solvents of decreasing polarity, typically encountered in RP-HPLC. This new technique, termed 'pseudo reversed-phase' HPLC, is gaining more and more importance for polyether characterization.

Both native PEGs or their alkyl/arylalkyl derivatives (Figure 16) are efficiently separated according to the number of repeat units and in particular, much better oligomer resolution of the former compounds is achievable compared with RP-HPLC. Exceptions are RP-HPLC on an NH_2 -bonded phase and ion exchange chromatography. However, despite this great advantage, retention rapidly increases with increasing M_r , but PEG 3000 is still separated into the maximum number of oligomers with an eluent system consisting of acetonitrile and water containing THF as the 'solubility modifier', as confirmed by MALDI-TOF/MS after conversion to its α,ω -bis(naphthylurethane) derivative (Figure 17). PEG samples with $M_r > 3000$ are strongly adsorbed onto the polar column matrix and can only be released from it with THF as the mobile phase modifier, but resolution vanishes completely.

Ion-exchange Chromatography (IEC)

Although lacking any ionizable groups, PEGs and their alkyl and/or arylalkyl derivatives can be separated by IEC, which is attributable to the unique properties of the 1,2-dioxoethylene structural units, being able to form five-membered cyclic complexes with alkali metal ions, such as K^+ . Separation of PEG

(Reproduced from Sun C, Baird M, Anderson HA and Brydon DL (1996) *Journal of Chromatography A* 731: 161–169, with permission from Elsevier Science.)

is achieved on either typical polymer-based cation exchangers (Figure 18) or on easily ionizable weakly basic stationary phases, such as NH_2 . In the latter case, retention occurs by complexation of PEG at the ammonium sites of the stationary phase, being protonated by use of a slightly acidic mobile phase, and competitive displacement of the solute with increasing concentrations of K^+ ions in the eluent. Optimum results are obtained with potassium perchlorate in methanol and resolution is achieved according to both hydrophobic moiety and number of repeat units. As expected, retention increases with increasing number of ethoxymers, but this effect is so large that already PEGs of $M_r \approx 2000$ are almost irreversibly retained on the column.

Liquid Chromatography under Critical Conditions (LCCC)

LCCC is a typical method used in polymer analysis as the first step of ‘two-dimensional’ chromatography. It is applicable in either normal or reversed-phase LC modes and separates mixtures of polymers according to their different chemical composition. In contrast to HPLC of polymers, requiring gradient conditions for efficient separation of homologues, LCCC is an isocratic technique.

In general, LC of polymers is governed by (i) exclusion, (ii) solubility and (iii) adsorption. Depending on both temperature and composition of the solvents and nonsolvents used all three modes can occur. In

Figure 17 Chromatogram obtained from 100 ppm of the α,ω -bis(1-naphthylurethane) derivative of PEG 3000 dissolved in 10 μ L THF on a Spherisorb Si 80 column (125 \times 4.6 mm, 5 μ m) with a ternary gradient of acetonitrile, water and THF (20% acetonitrile–80% water to 80% acetonitrile–20% THF in 40 min, followed by a drop to the starting conditions within 1 min and re-equilibration for 14 min (Reproduced from Rissler K, Wyttenbach N, Börnsen KO (2000) *Journal of Chromatography A*, in press, with permission from Elsevier Science.)

size exclusion a strong eluent is used, which ideally prevents enthalpic solute–stationary phase interactions affecting elution of sample constituents in the range of decreasing M_r . When the percentage of nonsolvent is raised, retention increases and changes more and more from pure size exclusion to precipitation or adsorption. A further increase of the percentage of nonsolvent affords pronounced solute–stationary phase interactions, resulting in separation of molecules proportional to their M_r . LCCC marks the transition point between size exclusion and adsorption. At this critical point of adsorption, complete compensation of the enthalpic as well as entropic terms of the solute's adsorption occurs. If polymers possessing different end groups differ in molar mass but not in chemical structure of repeat units are separated, a nonsolvent–solvent ratio can be found, at which oligomers merge into a common peak, regardless of their M_r . In this case, separation is

Figure 18 Typical separation in terms of POE chain distribution of POE(10)O (left) and POE(20)O (right). Mobile phase, methanol (0–3 min) to 7.5 mM KCl in methanol (30 min). only achieved with respect of end group functionality, whereas molecular weight heterogeneity is not revealed (**Figure 19**). In a subsequent step, all components having identical end groups can be separated according to M_r by SEC.

Future Developments

Owing to its excellent resolving power, capillary zone electrophoresis (CZE) may play an increasing role in polymer separation and recent applications seem to be promising. The chemistry of the inner surface of the capillaries resembles that of open tubular HPLC and therefore, a wide variety of materials ranging

from strongly polar (silica gel coated) to strongly hydrophobic (C_{18} coated) as well as gel-coated (e.g., PAGE) capillaries are available. Whereas CZE of polyethers as well as the NIS-based derivatives require derivatization with, e.g., phthalic anhydride or trimellitic acid anhydride yielding one and two free

carboxy groups, respectively, per hydroxy function, the polyether amines are amenable to classical electrophoresis. Nevertheless, derivatization of neutral analytes with a charge-creating agent is not an ultimate prerequisite, because polymers can also be separated by micellar electrokinetic capillary chromatography (MEKC). Optimum separation efficiency of PEGs is achieved in the capillary gel electrophoretic mode after derivatization with trimellitic acid anhydride and the whole amount of oligomers can be separated up to M_r 5000, as confirmed by MALDI-TOF/MS investigations (Figure 20). As in HPLC, detection is performed by monitoring either UV response in the usual wavelength range down to about 200 nm or FD and depends on the chromophore introduced by derivatization.

At least at the moment, CZE affords separation of PEG oligomers up to $M_r \approx 5000$. However, signal resolution is not unlimited and markedly depends on the ratio $\Delta m/M$ (m = mass of repeat unit, M = total mass of polymer), i.e., the lower the ratio $\Delta m/M$ the lower the differences in the interactive surfaces between polymer $M(n)$ and $M(n+1)$. Fortunately, mass spectrometry, due to its unsurpassable resolution, still yields oligomer differentiation when separation into individual oligomers by chromatographic techniques fails. Nevertheless, prior chromatographic fractionation is essential to obtain clear and well-interpretable mass spectra. In this respect electrospray ionization (ESI) TOF/MS performed on-line and MALDI-TOF/MS carried out off-line with the isolated fractions are the methods of choice. Whereas polar polymers, such as, e.g., polyethers, polyacrylic acid and its esters are easily ionizable, addition of silver salts facilitates ionization of nonpolar analytes, such as, e.g., polystyrene, polybutadiene, bisphenol-A-diglycidylethers or phenol-novolaks.

In conclusion, it is expected that chromatography coupled to MS and therefore affording optimum structural information, will be dominant in future applications.

POLYMER ADDITIVES: SUPERCRITICAL FLUID CHROMATOGRAPHY

T. P. Hunt, ICI Technology, Middlesbrough, UK

Copyright © 2000 Academic Press

Introduction

Commercial polymers contain small quantities of low molecular weight additives which are evenly dispersed throughout the polymer matrix. They are typically present at concentrations in the order of 0.1–1.0% (w/w) but can be as high as 60% w/w in certain formulations. They make an important contribution to the properties and suitability of particular polymer grades.

The analysis of polymer additives is a two-stage process. The additives are first separated from the polymer by solvent extraction or reprecipitation. The extracted additives are then separated and quantified by a suitable chromatographic technique. This article is concerned with the application of supercritical fluid chromatography (SFC) to this second stage. However this also involves a discussion of coupled supercritical fluid chromatography–supercritical fluid extraction (SFE-SFC) in which both stages are combined into a single analysis.

Polymer Additives

The most common polymer additives are stabilizers, plasticizers, lubricants and flame retardants. Stabilizers are added to prolong the useful life of a polymer formulation by protecting it from thermal and light-assisted oxidation. This process is caused by the formation in the polymer chain of free radical sites which can react with oxygen to form unstable peroxy radicals and ultimately cause polymer chain scission.

Stabilizers are divided into four main classes: UV absorbers, primary antioxidants, secondary antioxidants and quenchers.

UV absorbers such as benzophenones and triazoles screen the polymer from harmful photons by absorbing them and then dissipating the excitation energy as heat so there is no radical formation. Primary antioxidants are typically hindered phenols. They react with free radicals to prevent further propagation. Secondary antioxidants destroy the hydroperoxide sites on the polymer chain which could otherwise be converted to peroxy radicals. They tend to be sulfur- or phosphorus-containing compounds. Quenchers are usually organonickel compounds and their function is to take over the energy absorbed by the chromophores in the polymer and dissipate it as heat.

Lubricants are added to make the polymer easier to process by controlling the melt rheology during thermoplastic moulding. They optimize the properties of the finished article to create smooth and unblemished surfaces and minimize stress fractures. External lubricants are compounds that are added to a polymer blend to control the degree of adhesion and friction between the polymer melt and hot processing equipment. Internal lubricants are added to polymer blends to reduce the melt viscosity to facilitate lower processing temperatures and to improve heat dissipation. Many lubricants possess a combination of internal and external characteristics. Lubricants are typically fatty alcohols, acids and esters and hydrocarbon waxes.

Plasticizers are high-boiling, organic chemicals which are often present at high concentrations, solvating the polymer chains to form stable gels. As a result,

intermolecular forces are reduced and this leads to a lower polymer glass transition temperature. The polymer is consequently less brittle and more easily worked. Typical plasticizers are phthalates, adipates and polychlorinated hydrocarbons. Flame retardants are typically chlorinated organophosphates.

It is evident then that a vast number of chemical species are used as polymer additives. They have widely varying volatilities with molecular weights potentially varying from 200 to 1000 Da. They tend to be of low to medium polarity and many do not have UV chromophores. Polymer formulations contain unique combinations of additives (called additive packages) which often contain 10 or more compounds. Thus the identification and quantitation of these additive packages is a challenging chromatographic problem.

Advantages of SFC for Polymer Additive Analysis

The analysis of extracted polymer additives by means of chromatographic separation has been reviewed by Handley. Gas chromatography (GC) has been used to analyse plasticizers and some stabilizers. It has the advantage of employing the near-universal flame ionization detector (FID) as the standard detector. Many additives, however, are not volatile enough to be efficiently separated by GC and, although high temperature GC has made recent advances, this approach is not suitable for most stabilizers because they tend to be thermally labile. This has led to liquid chromatographic techniques being favoured. Gel permeation chromatography (GPC) and high performance liquid chromatography (HPLC) methods have been developed. GPC has the wider molecular weight range but its use is severely limited by its inferior resolution compared to HPLC. Unfortunately, HPLC separations tend to employ gradient elution and this necessitates the use of UV detectors. This means that conventional HPLC is not applicable to the analysis of additives which lack a UV chromophore.

SFC has been widely applied in the analysis of polymer additives. It is a potentially attractive alternative because it can combine a compatibility with the universal FID detector with a capability to elute high boiling components at lower temperatures than GC. This capability arises from the properties of the supercritical fluid (SF) which is the mobile phase in SFC. This is a dense fluid which is above or near its critical temperature and pressure. It has solvating properties, which are similar to those of a liquid, and transport properties which approach those of a gas. The enhanced solubility of high-boiling polymer ad-

ditives in a SF compared with their solubility in a gas enables them to be eluted at much lower temperatures than is possible for GC. SFC also compares favourably with LC because of the higher binary diffusion coefficients and the lower viscosities of the SF compared to the liquid phase. The higher diffusion coefficients of polymer additives in an SF give enhanced resolution. The lower viscosity results in a lower pressure drop across an analytical column and this means that higher flow rates can be used to give faster separations. SF mobile phases have been used with both packed and capillary columns to achieve polymer additive separations.

Capillary Column Separations

Capillary SFC separations of polymer additives are performed using conventional GC columns with modified polysiloxane-bonded stationary phases. Unmodified carbon dioxide is used as the mobile phase. Reported separations typically use columns of 50 or 100 μm internal diameter (i.d.) with typical film thicknesses varying from 0.05 to 0.5 μm . These narrow-bore columns are required to achieve an equivalent resolution to the 250–320 μm columns, which are used in conventional GC, because the diffusivity range of supercritical carbon dioxide is lower than that of a GC carrier gas. Similarly, the relatively short 10 m column length reflects the higher viscosity of supercritical carbon dioxide.

Capillary columns in SFC tend to be characterized by better resolution than packed columns; however, they also have an inferior sample capacity and produce longer analysis times.

Capillary SFC is carried out using GC analysers which are modified by the addition of a high pressure pump to deliver liquid carbon dioxide to the top of the column. The other end of the column is connected to the FID via a pressure restrictor which accounts for most of the pressure drop in the system. This allows the column pressure to be controlled by increasing the flow rate until the required level is achieved. The earliest restrictors were approximately 10 cm lengths of 5–10 μm fused silica but these have subsequently been replaced by frit and integral restrictors. The limitation of this type of fixed restrictor is that independent control of both flow and pressure is impossible. The pressure is controlled by changing the flow rate and vice versa. Pressure programming is always used for polymer additive separations. Typical flow rates are very low and this means that syringe pumps with their superior performance are routinely used. Capillary SFC is compatible with all GC detectors, including the FID; however, the depressurization of carbon dioxide through the restrictor results in Joule-Thompson cooling of the detector and relative-

Figure 1 Chromatogram of polymer additive standards on a 10 m \times 50 μ m i.d. Octyl column at 110°C. Mobile phase: carbon dioxide pressure programmed from 129 atm (12 min) to 350 atm at 3 atm min⁻¹. (Reproduced with permission from Moulder *et al.* (1989).)

ly high FID temperatures (300–400°C) are required to compensate for this effect.

Polymer additive separations tend to be performed isothermally at temperatures between 80 and 140°C. The additives are eluted by means of a pressure/density gradient. The column pressure is initially held at a low pressure (8–15 MPa) for 5–10 min to allow the solvent to elute through the system while the less soluble additives are retained at the top of the column. The pressure is then increased at a rate of between 0.25 and 1 MPa min⁻¹ to reach a final pressure of 35–45 MPa. Those additives which have the highest solubility in the mobile phase are solvated at lower pressures and consequently are eluted first. Additives with lower solubilities elute later. Many additive packages are composed of components with similar polarities and their solubilities and hence their retention times are largely determined by their molecular weights, with lighter molecules eluting first. A typical chromatogram is shown in **Figure 1**.

A wide range of additives have separated using polysiloxane phases. These include phenolic antioxidants, benzotriazoles, thioesters, organophosphite and organometal stabilizers; fatty acid, ester and amide lubricants; and organophosphate flame retardants. Methyl, octyl, phenyl and biphenyl substituted stationary phases have been used. Biphenyl columns have been found to give better separations than methyl columns and their use has dominated in later publications.

Packed Column Separations

These are divided into two distinct categories: separations on 1 mm (i.d.) columns of lengths between 10 and 40 cm; and separations on conventional 4.6 mm (i.d.) \times 20–25 cm (length) HPLC columns. The stainless-steel columns are packed in both cases with 5 μ m particles of bonded silica. Packed column SFC

has been used to elute phenolic antioxidants, benzotriazoles, thioesters and organophosphite stabilizers, fatty ester and amide lubricants and phthalate plasticizers.

Separations on 1 mm columns are similar to those on capillary columns. They are performed using capillary SFC instrumentation with the pressure restrictor adjusted to give a higher flow rate range. Unmodified carbon dioxide is used as the mobile phase, the column is operated isothermally at 100–150°C and the additives are eluted with a pressure programme. The pressure is initially held at 10–15 MPa and then increased at 0.5–1.2 MPa min⁻¹ to a final pressure of 35–45 MPa. Nonpolar octadecyl phases are most commonly used for these separations; however, more polar octyl, phenyl and polyethylene glycol phases have also been used. A typical separation is shown in **Figure 2**. Packed columns are more active than capillaries and this can lead to peak tailing for more polar additives. This tailing can be minimized by adding a polar modifier to the carbon dioxide mobile phase at approximately 1% (v/v). Formic acid is commonly used for this purpose it has a low FID response. An alternative approach is to use 250–320 μ m (i.d.) fused silica columns which are packed with bonded silica particles. These packed capillary columns exhibit lower activity than conventional packed columns and they generate flow rates which are more compatible with the FID.

Separations on 4.6 mm columns resemble normal-phase HPLC separations. The column is operated isothermally at the lower temperature range of 40–60°C and isobarically with the pressure set to 10–20 MPa with the flow rate set to 2–4 mL min⁻¹. The additives are eluted by means of a composition

Figure 2 Chromatogram of polyethylene additives on a 25 cm \times 1 mm i.d. C₁₈ column at 150°C. Mobile phase: carbon dioxide pressure programmed from 1500 psi (6 min) to 6000 psi at 200 psi min⁻¹. Peaks: 1, Tinuvin 326; 2, Irgafos 168; 3, Irganox 1076. (Reproduced with permission from Ryan *et al.* (1990).)

Figure 3 Chromatogram of polymer additives on a 25 cm \times 4.6 mm i.d. C_{18} column. Mobile phase: carbon dioxide/methanol at 200 bar and 2 mL min^{-1} . gradient of a polar modifier (usually methanol) in carbon dioxide. They are sequentially desorbed from the stationary phase as the polarity of the mobile phase increases. The elution order in such separations is determined by the relative adsorption strengths of the additives which in turn are determined by their functional groups and polarities. Hence, the least polar additives elute first and more polar additives elute later. Polar cyano, amino and diol phases are best suited to this mechanism; however, octadecyl columns can also be used due to the presence of residual silanol groups. A typical composition gradient separation is shown in Figure 3.

Composition gradient separations are performed using modified HPLC instrumentation. The high flow rates necessitate the use of binary piston pump systems. The larger system volume allows the use of back-pressure regulators which give independent control of both pressure and flow rate. UV detectors are used because organic modifiers are not compatible with the FID.

Offline Analysis: Sample Injection and Calibration

Sample introduction in SFC is achieved using HPLC-type high pressure injection valves. A fixed-volume injection loop is filled with the additive solution, then switched into the SF flow path and swept on to the column. A 200 nL loop is typically used in capillary SFC; however, even this volume is sufficient to overload a 50 μm column. Hence, flow split and time split techniques are used so that only a fraction of the 200 nL aliquot is introduced into the column.

Time split injection is a convenient procedure for routine analysis. It does not suffer from the problem

of additive molecular weight discrimination, which is associated with flow split injection, but it gives poor additive peak area repeatabilities (10–20%) and the low sample capacity also leads to relatively poor sensitivity. The lower limit of detection (using FID) for a single additive solution, which is injected in time-split mode on to a 50 μL column, is approximately 100 p.p.m. (w/v). For a 5 mL extract of a 5 g polymer sample this is equivalent to 100 p.p.m. (w/w) concentration of the additive in the polymer. This detection limit should be an adequate characterization of most polymer additive packages; however, it is not sufficient for studies on the migration of additives into food simulants where there is a requirement to detect additives in food simulants at p.p.b. levels. Greater sensitivity can be achieved by means of large volume injection/solvent venting techniques.

The sample capacity of a packed column in SFC compares favourably with HPLC and a similar range of sample volumes (5 μL –1 mL) is employed. This means that it is possible with packed column SFC to achieve the p.p.b. (w/v) level limits of detection which are required for additive migration work.

The sample injection repeatability is similar to that obtained in HPLC and this means that multi-level external standards can be used for the additive peak area–concentration calibration. The poor repeatability of capillary SFC injection, conversely, means that in this case an internal standard must be used for calibration.

Online SFE-SFC

Online SFE-SFC has been reviewed by Levy and Ashraf-Khorassani. The polymer is analysed in a single process without any intermediate preparation. It involves the transfer of the whole of the SFE extract on to the SFC analyser and this means that online SFE is more sensitive than equivalent offline procedures where the extract is diluted in an aliquot of solvent for subsequent injection on to an analyser. Hence it is ideally suited for trace analysis or for applications where there is little available sample. However the counterpoint of this argument is that the sample size is limited by the capacity of the interfaced analyser. This can be a disadvantage. Additives should be evenly dispersed throughout a batch of polymer chips. However, in practice, process faults can cause localized variations so that the additives are more concentrated in some chips than in others. In this circumstance it is clearly important for a representative analysis to be able to sample from more than one chip.

The most widely used coupling system is called cryotrapping. This involves feeding the SFE outflow

into a vented collection tee or retention gap which is cooled by adiabatically vaporizing liquid CO_2 through it. The extracted analytes are deposited in the retention gap during the extraction whilst the SF is vented to the atmosphere. When the extraction is complete the vent is closed and deposited analytes are eluted by the SF into the column.

Calibration curves for quantitative analysis can be obtained from online extractions on known amounts of free additive. These are then used to convert the online additive peak areas from the polymer extraction into concentration values. However, the validity of this approach depends on the complete removal of the additives from the polymer during the SFE step. Alternatively, the system can be calibrated using similar polymer samples of known additive concentration. It is not necessary with this procedure completely to extract all of the polymer additives so long as the extraction conditions for the polymer sample and standard are identical.

Identification of Unknown Additives

FID and UV detection are sufficient for the analysis of an additive package of known composition. The order of the eluting peaks is determined in this case by comparing their retention times with those of the pure additives, eluted under identical conditions; however, this procedure is clearly impossible for the identification of a mixture unknown additives. Hence there is a requirement for the SFC separation to be coupled with a spectroscopic technique which records sufficient structural and fingerprinting data on the eluting additive to enable it to be identified either by deduction or by comparison with library records.

Fourier transform infrared (FTIR) spectroscopy can be coupled indirectly to capillary SFC by depositing the additive on to an infrared disc or directly by passing the column outflow through a flow cell. The latter technique is possible because carbon dioxide exhibits just two narrow absorption bands in the near infrared spectrum. Alternatively xenon, which is completely transparent to infrared, can be used as the mobile phase. Both interfaces have been successfully used to identify a wide range of stabilizers; however, they lack sensitivity and quantitative measurements have not been achieved. The poor sensitivity necessitates the use of 100 μm i.d. columns.

Carbon dioxide is a nonprotonated solvent and this makes SFC the ideal chromatographic technique to couple with ^1H nuclear magnetic resonance (NMR). The relatively large dead volume of the NMR probe means that it can only be interfaced with packed column SFC with flow rates $>1\text{ mL min}^{-1}$ and

sample loadings of 20–120 μL . This procedure has been used to analyse phthalate plasticizers. Unfortunately, SFC-NMR signals have been found to be pressure-dependent and exhibit increased spin-lattice relaxation times.

SFC has been most successfully coupled to mass spectroscopy (MS). MS detectors can be used in several modes to give molecular ion data and structural data from fragmentation patterns which can be compared with library records to identify an unknown additive. Total ion chromatograms can also be used for quantitative analysis. Capillary SFC is interfaced directly by feeding the end of the column into the ionization chamber of the MS. The MS signal is not affected by the SFC pressure gradient. This has been used for the identification and quantitation of flame retardants from polyurethane foams. Several interfaces (moving belt, thermospray, particle beam) have been used to couple packed-column SFC and MS. These tend either to inhibit the range of compatible SFC conditions or result in the loss of volatile components. The most promising system is currently atmospheric pressure chemical ionization MS which has been used with a carbon dioxide-methanol composition gradient to identify and quantify benzotriazoles and phenolic stabilizers.

Conclusion

SFC is a useful technique for the analysis of a wide range of polymer additives. It can elute nonvolatile and thermally labile additives which are not suitable for analysis by GC and it gives better resolution and faster separations compared with HPLC. Useful separations are obtained with both packed and capillary columns. Capillary separations generally involve 50 μm i.d. columns and FID detection with unmodified carbon dioxide used as the mobile phase. The additives are eluted with a pressure/density gradient. Packed columns with i.d. $<1\text{ mm}$ can also be operated in this way; however, separations on 4.6 mm i.d. columns employ composition gradients at a fixed temperature and pressure with UV detection. Capillary SFC generally gives separations of superior resolution but with longer analysis times and poor sensitivity.

The flexibility of SFC as a technique for the analysis of polymer additives is further enhanced by the ease with which it is interfaced to other techniques. SFE-SFC enables the detection of trace levels of additives which could not be analysed by offline procedures. SFC-FTIR, SFC-NMR and SFC-MS give the capability to determine the chemical structures of additives from polymer samples of unknown compositions.

POLYMERS

Field Flow Fractionation

Introduction

Two subtechniques of the field-flow fractionation (FFF) family are used to separate polymers with high resolution on an analytical scale; these are thermal FFF (ThFFF) and flow FFF (FIFFF). For lipophilic polymers, ThFFF excels in the analysis of high-molecular-weight-polymers ($M > 10^6 \text{ g mol}^{-1}$) and gel-containing polymers. ThFFF can also separate polymer blends and copolymers according to chemical composition. For hydrophilic polymers, FIFFF compares well with size-exclusion chromatography (SEC) for the analysis of polymers with $M > 10^3 \text{ g mol}^{-1}$, and like ThFFF, excels when

$M > 10^6 \text{ g mol}^{-1}$. By varying factors that control retention, each FFF application can be optimized, and programming such factors allows highly polydisperse samples to be analysed with unparalleled precision in a single run. FFF channels are more expensive than SEC columns, but with proper maintenance, channel lifetimes are virtually unlimited.

FFF, like liquid chromatography, relies on the differential migration of dissolved or suspended materials as they are flushed through a conduit. Unlike chromatography, however, the FFF separation relies on interactions of the analyte with an applied field rather than a stationary phase. As a result, the FFF separation occurs in a single phase (see **Figure 1**) with minimal exposure to surfaces, and the flowing liquid has a laminar profile. These features make for a gentle separation, so that fragile molecules and molecular complexes can be characterized with little disruption.

FFF instrumentation (**Figure 2**) is similar to that for chromatography, and consists of a pump to drive the carrier liquid, an injection port, the separation channel, and a detector to monitor the channel effluent.

Figure 1 Illustration of the separation mechanism in FFF. The field compresses larger material into a thinner layer against the accumulation wall, where they move more slowly.

A computer is used to control the applied field and to store the detector signal. Samples are injected with a microsyringe, either directly or via an injection valve.

One of the greatest strengths of FFF is its ability to directly measure physicochemical parameters on analyte components using well-defined models of retention. In FIFFF, for example, the diffusion coefficient (D) can be calculated directly from a component's

retention time. From D , the hydrodynamic size can be calculated, and if the intrinsic viscosity is measured independently, the molecular weight can be determined. Molecular weight can also be obtained directly from retention measurements through calibration standards. In ThFFF, D values can also be calculated from measured retention times once an additional parameter for each polymer type is obtained, as discussed below. An additional advantage

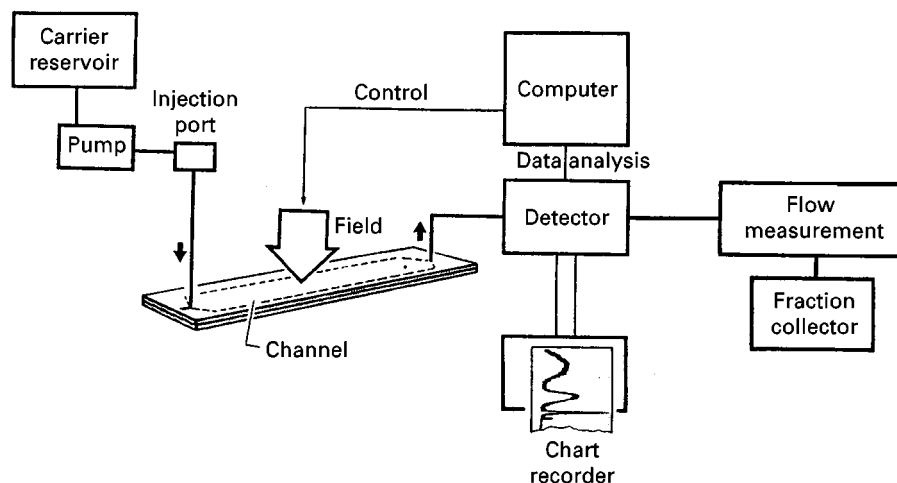

Figure 2 Schematic diagram of the FFF instrument.

of ThFFF is that band broadening is well defined, allowing for the determination of highly precise molecular-weight determinations.

Besides its placid nature and theoretical tractability, another attractive feature of FFF is its applicability to a wide variety of materials and situations. For example, FIFFF has been used to separate materials ranging in size from 10^3 to 10^{18} g mol $^{-1}$. However, flexibility comes with a price, and the user must understand the separation mechanism in order to apply FFF to new and different samples with efficiency. Outlined below are the more common applications of both ThFFF and FIFFF for polymer analysis with comparisons, when appropriate, to SEC.

Principles and Theory of Retention

The FFF channel has the shape of a ribbon (Figure 1), with a length of typically 30–50 cm, a breadth of 1–3 cm, and a typical thickness of 0.05–0.25 mm. A stream of carrier liquid is introduced at one end of the channel and exits at the other end. Since the channel has a high aspect ratio, the flow of carrier liquid is laminar, with a parabolic velocity profile across the thin dimension. A field is applied across the thin dimension, and a mixture to be separated is injected at the inlet end of the channel. As the mixture is transported by carrier liquid to the outlet, interactions with the field compress the sample against one wall, where slower streamlines exist. The concentration of sample at the accumulation wall is opposed by diffusion, and the result is a sample cloud with a concentration that decreases exponentially with distance from the wall. Components that interact differently with the field will form zones of different thickness at the accumulation wall. The dependence of zone thickness l on the force F of the interaction with the field is:

$$l = kT/F \quad [1]$$

where k is Boltzmann's constant and T is temperature. The thickness of the zone determines the extent to which its migration through the channel is reduced.

The extent to which an analyte is retained in FFF can be specified, as in chromatography, by its retention ratio R :

$$R = t^\circ/t_r = V^\circ/V_r \quad [2]$$

where t_r and V_r are the time and volume of carrier liquid, respectively, required to flush a component through the channel; the void time t° and void volume V° are the analogous parameters for a component

that does not interact with the field. The dependence of retention ratio R on zone thickness l is:

$$R = 6\frac{l}{w} \left[\coth\left(\frac{1}{2l/w}\right) - 2\frac{l}{w} \right] \quad [3]$$

The ratio l/w is given the symbol λ , and is referred to as the retention parameter, since it alone describes the relative migration of a component zone. As $\lambda \rightarrow 0$, $R \rightarrow 0$, and the analyte does not move through the channel. As $\lambda \rightarrow \infty$, $R \rightarrow 1$, and the analyte moves at the average velocity of the carrier liquid. As λ is reduced, the bracketed term in eqn [3] approaches unity, so that for many applications the relationship between R and λ is described by the following simple equation:

$$R = 6\lambda \quad [4]$$

The retention ratio of an eluting component can be determined experimentally through eqn [2] and translated into a λ value using eqn [3]. Values of λ , in turn, can be related to physicochemical properties of the analyte, as discussed below.

The properties that govern F (or λ) vary with the nature of the applied field, i.e. with the FFF subtechnique. In all sub-techniques, however, retention varies directly with the magnitude of the applied field. This relationship facilitates tuning the field in order to optimize each application, so that routine analyses can be performed with maximum efficiency. For highly polydisperse samples, the magnitude of the field can even be programmed in order to reduce the separation time of such samples. Field programming is analogous to temperature programming in gas chromatography and gradient elution in liquid chromatography. Figure 3 illustrates the ThFFF separation of seven polymer standards ranging in M from 9000 to 5.5×10^6 g mol $^{-1}$ in a single run.

Thermal FFF

In ThFFF, the applied field is a temperature gradient formed by heating and cooling, respectively, the two walls that define the thin dimension of the channel. A schematic of the ThFFF channel is illustrated in Figure 4. When placed in a temperature gradient, polymers migrate toward the lower temperature. This effect, which is known as thermal diffusion, governs the retention parameter (λ) in the following way:

$$\lambda_{Th} = \frac{D}{D_T \Delta T} \quad [5]$$

Here D_T is the coefficient of thermal diffusion, which relates mass flux to a temperature gradient, and ΔT is

Figure 3 Separation of a seven-component mixture by ThFFF with field programming. Values above peaks are molecular weights expressed as $\times 10^3 \text{ g mol}^{-1}$. the temperature drop across the channel. Equation [5] is actually an approximation because of an assumption that the temperature gradient is constant; this is not strictly true because solvent thermal conductivity changes with temperature across the channel. In fact, eqn [3] is also an approximation for ThFFF because of the temperature dependence of the solvent viscosity, which leads to a skewed velocity

profile. Various approaches have been used to refine eqns [3] and [5] in order to account for such temperature effects (see Martin, 1998), but for routine polymer analysis such refinements are not necessary.

The dependence of λ_{Th} on D/D_T means that neither D nor D_T can be computed by itself, only the ratio D/D_T . Fortunately, D_T is independent of molecular weight and branching configuration for a given polymer-solvent system, at least for random-coil homopolymers. As a result, λ_{Th} is a linear function of D for a given system when ΔT is held constant. Thus, once D_T is determined for a given system, values of D can be calculated directly from measurements of λ_{Th} in that system.

Since D_T is independent of molecular weight M , the separation of polymers by ThFFF is rooted, like SEC, in the dependence of D on M ; that dependence is given by the following expression:

$$D = \frac{kT}{6\pi\eta_0} \left(\frac{10\pi N_A}{3M[\eta]} \right)^{1/3} \quad [6]$$

where η_0 is the viscosity of the solvent, N_A is Avagadro's number, and $[\eta]$ is the intrinsic viscosity of the polymer. The relationship defined by eqn [6] forms the basis for universal calibration in SEC, and is applicable to ThFFF provided D_T is known for each polymer-solvent system to which the universal calibration is applied.

Figure 4 Basic design of the ThFFF channel, which is formed by a spacer sandwiched between two nickel-coated copper bars. One of the bars is heated while the other is cooled.

Flow FFF

In FIFFF, the applied field is a flow of carrier liquid across the thin dimension of the channel. This cross-flow is made possible by constructing one or both channel walls with a fritted material that is permeable to the carrier liquid (Figure 5). As a result, the flowing liquid has two perpendicular vectors. The axial-flow vector lies along the length of the channel, has a parabolic velocity profile across the thin dimension, and carries sample through the channel as in other FFF subtechniques. The cross-flow vector is directed across the channel, has a relatively flat velocity profile, and serves as the applied field by physically transporting material to the accumulation wall. A semipermeable membrane placed against the accumulation wall prevents analyte from penetrating the wall, while allowing the carrier liquid to pass through.

FIFFF employs one of two channel designs.

- In the symmetric design (SyFIFFF), both the accumulation wall and the (opposite) depletion wall are

Figure 5 Basic design of the flow FFF channel. In the symmetrical channel (top), the channel spacer is sandwiched between two frits, which allow carrier liquid to flow across the thin dimension of the channel. In the asymmetrical channel (bottom), a solid plate replaces the upper frit, which is transparent in order to see inside the channel during operation.

porous, and the axial flow and cross flow are controlled independently with separate pumps.

- In the asymmetric design (AsFIFFF), the depletion wall is replaced with a glass plate so that a single inlet stream serves as the source for both axial flow and cross flow.

The relative magnitudes of the two flow vectors are controlled by adjusting the relative amount of back-pressure applied at the axial outlet versus the cross-flow outlet. In contrast to the symmetric design, the axial velocity diminishes along the length of an asymmetric channel as fluid is lost through the accumulation wall. To compensate for this effect, the width of the asymmetric channel is tapered from inlet to outlet. However, except for a specific ratio of cross-to-axial flow rates, the axial velocity will still vary along the length of the channel. Therefore, for AsFIFFF, eqn [3] is not valid and must be replaced with:

$$R = \frac{t^\circ}{t_r} = \frac{6}{w} \frac{\int_0^w e^{(-x/l)B(x)} x dx - \frac{1}{w} \int_0^w e^{(-x/l)B(x)} x^2 dx}{\int_0^w e^{(-x/l)B(x)} dx} \quad [7a]$$

Here x is the distance from the accumulation wall:

$$B(x) = 1 - \frac{x^2}{w^2} + \frac{x^3}{2w^3} \quad [7b]$$

and:

$$t^\circ = \frac{V^\circ}{V_C} \ln \left(1 + \frac{V_C}{V_{out}} \left\{ 1 - \frac{w \left[b_o z' - \frac{(b_o - b_L)(z')^2}{2L} - y \right]}{V^\circ} \right\} \right) \quad [7c]$$

where V_C and V_{out} are the volumetric rates of flow thorough the cross-flow and axial-flow outlets, respectively. Parameters b_o and b_L are the breadths of the channel at the sample inlet and outlet, respectively, z' is the distance between the carrier inlet and the focusing position (discussed below), and y is the area reduction of the accumulation wall due to the tapered inlet (see Figure 5).

Asymmetric channels have two primary advantages: (1) they are less costly, and (2) the inside of the channel can be seen through the glass plate. By observing the motion of an injected dye, flow irregularities caused by a poorly sealed channel are easily visualized. On the other hand, the advantages of the

symmetric design are: (1) the axial flow and cross flow can be controlled independently, and (2) the equations relating R to λ are simpler.

In both FIFFF channel designs, the cross flow pushes all components with the same velocity (U) toward the accumulation wall. As a result, only the opposing motion of diffusion governs retention:

$$\lambda_F = \frac{D}{Uw} = \frac{DV^\circ}{V_c w^2} \quad [8]$$

Like ThFFF, the well-established inverse dependence of λ on field strength imparts flexibility and allows field programming, so that the most efficient possible method can be developed for each application.

Application to Polymer

Within the FFF family, the choice between thermal and flow FFF is a simple one for polymer analysis. In general, FIFFF is used for hydrophilic polymers, while ThFFF is best suited to lipophilic polymers. In either case, an advantage that FFF has over SEC is its greater peak capacity. In principle, V_r is unlimited in FFF, although 20 channel volumes represent a practical limit. In SEC, V_r is limited at the high end by the permeation volume (equal to one column volume), and at the low end by the exclusion volume.

Lipophilic Polymers

For lipophilic polymers with $M < 10^4 \text{ g mol}^{-1}$, ThFFF suffers from a lack of resolution, therefore SEC is almost mandatory, and certainly preferred. However, above 10^4 g mol^{-1} , the resolving power of ThFFF increases rapidly, and exceeds that of SEC for $M > 10^5 \text{ g mol}^{-1}$. For ultra-high molecular-weight polymers ($M > 10^6$), SEC becomes increasingly limited by shear-induced fragmentation of the chains as they travel through the packed bed under high pressure, and ThFFF is clearly superior.

Between 10^4 and 10^6 g mol^{-1} , neither SEC nor ThFFF has an overwhelming advantage for the analysis of many polymers. In general, ThFFF is more difficult to implement than SEC because there are more factors under the control of the user that influence retention. While this adds flexibility, only by understanding the separation mechanism and governing equations can one avoid certain pitfalls in choosing the proper parameters for each application.

For analysing certain types of lipophilic polymers, ThFFF has some rather unique advantages. The absence of shear forces, which make ThFFF especially suited to ultra-high molecular-weight polymers, was mentioned above. Using re-injection techniques, and

the absolute measurement of M by light scattering, the integrity of ThFFF analyses on high molecular-weight polymers that degrade in SEC columns has been clearly demonstrated. The open ThFFF channel is also amenable to gel-containing polymers. Since sample filtration is not required, microgels are not lost in the analysis, and an estimate of the gel content can even be obtained. ThFFF is also well suited to polyolefins, which are difficult to separate by SEC because high temperatures ($> 130^\circ\text{C}$) are required for their dissolution. At these temperatures, column packings used in SEC tend to degrade at an elevated rate, while the ThFFF channel is more robust.

Although the thermal diffusion coefficient D_T is independent of molecular weight, it varies with polymer composition. As a result, ThFFF can resolve polymer components that differ chemically even when their diffusion coefficients (or hydrodynamic volumes) are identical. This is in contrast to SEC, where components with similar diffusion coefficients cannot be separated. The dependence of retention on polymer composition can be used to separate copolymers according to composition, and when the dependence of D_T on copolymer composition is known, the chemical composition can be calculated from retention data. Such is the case for random (statistical) copolymers, where D_T is a weighted-average of the D_T values of the homopolymer constituents, with the weighting factors being the mole-fractions of each component in the copolymer. Thus, by measuring the retention of a copolymer of unknown composition, its D/D_T value can be calculated using eqns [3] and [5]. With an independent measure of D , a value for D_T can be calculated, and from D_T the copolymer composition. For block copolymers, a linear dependence of D_T on composition requires the polymers to be dissolved in a non-selective solvent, which is a solvent that is equally good for all copolymer components. Unfortunately, with highly branched block copolymers, even a non-selective solvent will fail to yield a linear dependence.

ThFFF is incapable of resolving the components of certain polymer mixtures. For example, when the composition of a polydisperse copolymer changes with molecular weight, two components that differ in both molecular weight and composition may have the same D/D_T ratio, even though their individual values of D and D_T differ. Such components will co-elute, in which case the combination of SEC and ThFFF is extremely powerful. Components can first be separated according to differences in D using SEC, then fractions from the SEC column, which are homogeneous in D , can be further separated according to D_T by ThFFF. Figure 6 illustrates such a combination applied to a polymer-copolymer mixture that neither

Figure 6 Cross-fractionation of a three-component polymer mixture by SEC and ThFFF. The mixture could not be sufficiently resolved for characterization by either SEC (top) or ThFFF (middle) alone. Cross-fractionation of SEC elution slices (bottom) provided enough resolution to determine the molar mass of each component with a multi-angle light-scattering detector (Dawn DSP, Wyatt Technology, Santa Barbara, CA). The composition of the components were determined from D and D_T values calculated from SEC and ThFFF retention volumes, respectively.

SEC nor ThFFF alone can separate. By cross-fractionating the mixture, the three components were sufficiently resolved to determine both the molecular weight and composition of each component.

Highly precise information on the polydispersity of lipophilic polymers can be obtained with ThFFF because column dispersion is well modelled, and its effect on the elution profile can therefore be removed. For example, plots of plate height H versus flow rate are linear. Such plots can be extrapolated to zero flow rate to yield an intercept term from which the sample polydispersity can be calculated. This method is used to obtain highly precise measurements of the polydispersity ($\mu < 1.005$) of polymers prepared by anionic polymerization. By comparison, the precision of SEC for such measurements is reduced by an order of magnitude because of uncertainties in the contribution of column dispersion to plate height. For a more detailed analysis, a well-defined band-broadening function can be mathematically removed from the elution profile to obtain highly precise molecular-weight distributions. With more polydisperse polymers ($\mu < 1.005$), column dispersion is nearly negligible in ThFFF when typical flow rates are used, so that elution profiles can be converted directly into accurate molecular-weight distributions.

Hydrophilic Polymers

For analysing hydrophilic polymers, FIFFF shares many of the advantages and limitations of ThFFF when compared to SEC. A notable difference is that FIFFF can be extended to lower molecular weights (10^3 g mol^{-1}). Another difference is that the effects of column dispersion cannot be completely removed from a FIFFF elution profile because of factors associated with the accumulation wall membrane.

SEC has been criticized for its lack of consistency in the separation of charged polymers. Part of the problem with SEC is attributed to interactions with the packing material. These interactions are often referred to as 'nonexclusion effects'. Electrolytes can be used to minimize such effects, but the conditions required to avoid both adsorption and repulsion are rather specific to each polymer, and are typically found through trial and error. Verification that an SEC separation is dominated by differences in D or M rather than interactions with the packing material can be a time-consuming process, and still not guarantee the accurate analysis of nonstandard samples. In FFF, the surfaces available for interactions with the sample are greatly reduced by the absence of packing material. Interactions with the accumulation wall can still be a factor, however, since samples are compressed against the wall by the applied field. However, they are less of a problem in FIFFF compared to SEC, and this allows for a wider range of aqueous solutions to be used in the analysis of charged polymers.

Figure 7 Separation of poly(ethylene oxide) standards by FIFFF. The cross-flow field was programmed to exponentially decay (decay-time constant 8 min) from an initial value of 5.9 mL min^{-1} . Values above peaks are molecular weights expressed as $\times 10^3 \text{ g mol}^{-1}$. Reprinted with permission from Kirkland JJ, Dिल्s CH Jr and Rementer SW (1992) Molecular weight distribution of water-soluble polymers by flow field-flow fractionation. *Analytical Chemistry* 64: 1295–1303. Copyright © 1992 American Chemical Society.

FIFFF has been applied to a wide variety of hydrophilic polymers. **Figure 7** illustrates the separation of poly(ethylene oxide) standards with an asymmetrical FIFFF channel using a programmed field. By decaying the field over time, four components ranging in M from 18 000 to 996 000 g mol^{-1} were resolved in 30 min.

Combined with a multi-angle light scattering (MALS) detector, FIFFF is being used to study the conformational dynamics of hydrophilic polymers in solution. Besides its ability to work within a wider range of solvent conditions, its broad size range is responsible for the unique ability of FIFFF–MALS to characterize the structural properties of such polymers in a partially aggregated state.

FIFFF is also being used to study copolymers. For example, the viscometric and aggregation properties of hydrophilic graft copolymers have been studied, as well as the micelle-forming behaviour of such copolymers. FIFFF has also been used to characterize the size and molecular weight of humic and fulvic acids, as well as to study changes in their conformation and aggregation properties as they occur over time upon alterations in solution properties.

Polysaccharides are another class of polymers that have proven difficult to separate by SEC. These materials have a wide range of industrial applications, from coating and packaging to plasma additives and blood substitutes. The physical, biological, and clinical properties of these materials vary with their molecular-weight distribution, which is generally quite broad. It is difficult to prepare robust SEC packings that are capable of analysing these fragile macromolecules without complications of sample adsorption, shear degradation and clogging of the column. FFF has been used to fractionate a wide variety of polysaccharides according to their molecular weight.

FIFFF is used to separate ultra-high molecular-weight polymers, as well as aggregates of lower molecular-weight polymers. For example, SEC fails to completely separate many dextran samples because of the exclusion boundary. The size and molecular weight of such samples are routinely characterized by FIFFF with MALS detection.

Determination of Molecular-Weight Distributions by FFF

The simplest calibration plots in thermal and flow FFF take the following form:

$$\log(V_r) = A + S_m \log M \quad [9]$$

where A and S_m are calibration constants for a given polymer–solvent system. Parameter S_m is termed the mass-based selectivity. However, at low levels of retention ($R > 0.2$), S_m changes with R . An alternate form of eqn [9] allows for the use of low levels of retention without losing linearity in the calibration plot:

$$\log(V_r - V^\circ) = A + S_m \log M \quad [10]$$

Equation [10] allows retention to be calibrated over a wide range in molecular weight for a given polymer–solvent system without requiring the calculation of retention parameter λ . The problem remains, however, that neither eqn [9] nor eqn [10] allows for an adjustment in field strength, which is one of the great benefits of FFF, as it allows the field to be optimized for each individual sample. In order to have a single calibration equation for different field strengths, one must incorporate the field strength S :

$$\log \lambda S = B + b \log M \quad [11]$$

The field strength S is the magnitude of the temperature drop (ΔT) across the channel in ThFFF, and the

Figure 8 Plot of $\log \lambda_T \Delta T$ versus $\log M$ for polystyrene samples, illustrating the validity of the calibration model expressed by eqn [11]. The cold wall temperature was 15°C and ΔT ranged from 8 to 81°C. The carrier liquids included tetrahydrofuran and ethylbenzene. A single plot can be used for both solvents because they yield a similar dependence of D/D_T on M for polystyrene. Copyright © 1985 American Chemical Society.

rate of cross flow (V_C) in FIFFF. By calibrating FFF channels in terms of $\log \lambda S$ versus $\log M$, the field strength can be changed to optimize the separation of a given sample without the need for re-calibration. Figure 8 illustrates calibration plots in the form of eqn [11] for ThFFF.

Compared to SEC, universal calibration equations in FFF have the potential for being much broader in scope. In SEC, a given column can be ‘universally’ calibrated and applied to several types of polymers of similar conformation, provided the intrinsic viscosity is also measured on all standards and samples. In FIFFF, the same concept can be applied, but D is measured directly, so that calibration is not required at all if viscosity is measured independently. In ThFFF, each polymer–solvent system requires a set of different calibration constants, but once such constants are determined, they are applicable to all ThFFF channels in the ‘universe’. Of course, the temperature can affect calibration constants, as it does in SEC. Therefore, in ThFFF, the cold wall temperature must be the same in all channels that use a given set of calibration constants.

Trends

FFF will continue to be utilized primarily for the characterization of ultra-high molecular-weight polymers, which are difficult to characterize by SEC. One of the fastest-growing areas for FIFFF is the study of hydrophilic systems that undergo complex interac-

tions. Such interactions are often the key to understanding biological activity in protein and nucleic acid complexes, as well as the complex rheological behaviour of polysaccharides. Regarding the application of ThFFF to industrial polymers, two applications will continue to expand. The first of these is the application to copolymers. As our understanding of thermal diffusion increases, the ability to extract compositional information from fractionated copolymer samples will grow. A growing number of scientists are researching this promising aspect of ThFFF technology.

The second area of growth is the application of ThFFF to the separation of colloidal materials. While this type of sample has been historically considered the domain of flow and sedimentation FFF, the unique ability of ThFFF to separate these materials by composition in both organic and aqueous carrier liquids is gaining the attention of several groups in both industry and academia.

The characterization of polymers will continue to benefit from the combination of FFF with informative detectors such as MALS, dynamic light scattering, intrinsic viscosity, and infrared detectors. For the last thirty years, the characterization of materials by FFF has relied on calibration with standards or the use of retention theory to extract analytical information. Calibration is limited by the availability of polymer standards, and while FFF has the unique ability to produce physicochemical parameters directly from retention theory (i.e. without calibration), this too has limitations. Absolute molecular-weight detectors produce molecular-weight values without the need for calibration curves. When a complex sample is first separated by FFF, a light-scattering detector produces a molecular weight value for hundreds or even thousands of relatively monodisperse components of the sample. The result is a highly accurate determination of the entire molecular-weight distribution of the sample. The combination of FFF–MALS has been particularly popular, as evidenced by the fact that greater than 20% of the papers presented at a recent FFF symposium involved MALS detection.

Introduction

Plastics are a mixture of the polymer itself and many small molecules. Some, such as antioxidants and plasticizers, are added to the polymer to alter the properties. Others, such as residual monomers, processing aids and feedstock contamination are present inadvertently. The levels of these compounds must be accurately known by manufacturers and regulators in order to assess whether the plastic is fit for its intended purpose. There are usually many compounds present in the plastic, which makes analysis of their levels whilst still in the plastic very difficult. Usually, therefore, the compounds must be separated from the bulk polymer before analysis. Conventional methods include liquid/solid extraction and dissolution followed by reprecipitation of the polymer. Conventional solvent extraction methods tend to be very slow, e.g. Soxhlet extraction may require 24 hours to complete, and the dissolution/reprecipitation methods may result in extracts contaminated by oligomeric ‘waxes’, requiring further clean up before

analysis. Methods producing clean, fast extracts are therefore very useful. The techniques of supercritical fluid extraction (SFE), pressurized fluid extraction (PFE) and microwave assisted extraction (MAE) have been shown to decrease extraction times, with lower use of solvents than conventional methods.

The Extraction Process

In SFE and PFE, the matrix is held in a cell, and the solvent is pumped into the cell under pressure. Commonly in SFE, the solvent is pumped continuously past the sample (dynamic extraction), dissolving the analyte molecule and carrying it out of the cell to be collected. In PFE it is more common for the solvent to be pumped until the cell is full, and then left for a period of static extraction. The analyte dissolves in the solvent, which is then flushed by more solvent from the cell to the collecting vial. MAE is carried out in one container, in which sample and solvent are placed. The solvent is heated by microwaves, and the analytes dissolve in the solvent. The vessel must then be allowed to cool before opening, and the extraction liquid can be separated from the extracted polymer by simple filtering. In simple terms, extractions with all methods can be thought of as proceeding in two

steps, movement of the extracting compound from the bulk polymer to the surface by diffusion, and then dissolution in the solvent. The rates of these two steps is influenced by several factors.

Factors Affecting Extraction Rate

Particle size The distance the molecule has to move affects the time it takes to reach the surface. Small particles and thin films are therefore preferred. For spherical particles, the rate of extraction is proportional to $1/(\text{radius})^2$. Thus grinding 3 mm beads to 0.5 mm particles should increase extraction rate 36 times. For complete extraction, it is the size of the largest particles which dictates the extraction time, not the average particle size. Sieving to remove the largest particles can increase extraction rates dramatically. Grinding polymers generates considerable heat, and this can cause loss of analytes by degradation or volatilization. Polymers are usually freeze-ground under liquid nitrogen to prevent loss of analyte. A problem with polymers is that the particles can easily stick together, increasing the effective particle size.

Rate of diffusion Diffusion is driven by the tendency of a material to move from an area of high concentration to low concentration. The rate of diffusion depends on the size of the concentration gradient and the diffusion coefficient, a measure of how easily the diffusing material can move through the matrix. The diffusion coefficient follows the Arrhenius equation:

$$D = D_0 \exp(-E/RT)$$

where D is the diffusion coefficient, E is the activation energy, T is the absolute temperature and R the gas constant. The diffusion coefficient will be greatest when E is small and T is large. Several factors affect the rate of diffusion, as outlined below.

Size of diffusing molecule Smaller molecules can more easily move through the matrix, hence activation energy is lower for smaller molecules and diffusion is faster.

Polymer matrix The more open the matrix, the lower the activation energy, and the faster the diffusion. The 'openness' of the matrix is affected by several factors. For polymers of the same type, the density gives a good indication. Thus diffusion is faster through low density polyethylene than high density polyethylene. The crystallinity of the polymer also has a large influence. The molecules in crystalline parts of a polymer are more highly ordered and

densely packed than the amorphous parts, and hence diffusion is much slower through crystalline than amorphous polymer. An important factor in extraction from polymers is therefore the glass transition temperature, T_g , at which the polymer moves from a glassy to an amorphous state. The diffusion is much faster at temperatures higher than T_g .

Temperature The temperature affects the diffusion directly, by the T term in the Arrhenius equation, and through effects on the polymer. From the Arrhenius equation, the temperature should be as high as possible to maximize D . However, at very high temperatures, the polymer will soften and melt. This will cause the particles to agglomerate, and hence slow down the extraction. High temperatures could also cause the extracting molecule to decompose or react. The extraction temperature should always be above T_g for the polymer, but below the softening point.

Solubility If the concentration of the material at the surface is higher than the solubility, the amount extracted will be limited to that which can dissolve in the solvent. This will in turn slow down the rate at which the material diffuses to the surface, as the concentration gradient will be smaller. In solubility limited extractions, the extraction rate can be increased by increasing the solvating power of the solvent. In SFE, this can be either by increasing the pressure or adding a modifier. Increasing the flow rate will dissolve more material in unit time, and, therefore, has a similar effect to increasing the solubility.

Models of Extraction

Mathematical models have been developed to describe the extraction process, using equations for diffusion and solubility. Two terms are defined, a diffusion term, D/a^2 , and a term proportional to solubility, ha , where a is the radius of the particles. The proportion of the total extracted (m/m_0 , where m is the amount remaining and m_0 the amount at time = 0) can then be defined in terms of these variables. Plotting $\ln(m/m_0)$ against time produces a characteristic shaped line, shown in **Figure 1(A)**. The amount remaining in the polymer falls rapidly at first, as the surface analyte is extracted. The plot then becomes linear, as the surface concentration falls and the extraction is controlled by the diffusion rate. The stages occurring during extraction can be illustrated by the concentration of analyte across a particle. **Figure 2(A)** shows a completely diffusion limited case, where ha is infinite. The concentration at the surface rapidly falls to zero, and the extraction is then

Figure 1 Plots of $\ln(m/m_0)$ for extractions with different solubilities. (A) = diffusion-limited extraction ('hot ball' model). (B) = intermediate solubility. (C) = solubility-limited extraction.

limited only by the rate at which analyte diffuses to the surface. This diffusion limited extreme is the 'hot ball' model, so called because it used modified equations describing the cooling of a hot sphere. The

opposite extreme is shown in **Figure 2(C)**, where, the diffusion is much faster than the ability of the solvent to remove analyte from the surface. The concentration gradient remains flat as the material is dissolved. The intermediate case shows the position where both solubility and diffusion play a significant part in the extraction. In each case, the initial step is the formation of the smooth concentration profile across the particle. This occurs during the sharply falling part of the $\ln(m/m_0)$ plot. After this, the profile retains the same shape, but reduces in size during the linear (exponential) part of the $\ln(m/m_0)$ plot.

Figure 2 Concentration profiles during extraction for different values of solubility. (A) $ha = \infty$. Corresponds to Figure 1(A), the 'hot ball' model, extraction completely diffusion-limited. (B) ha intermediate. Corresponds to Figure 1(B), solubility and diffusion both contribute to extraction rate. (C) $ha = 1$. Corresponds to Figure 1(C). Solubility-limited extraction.

Diffusion- or Solubility-limited?

The strategies required to optimize an extraction often depend on the limiting factor, solubility or diffusion. Often, both will play a significant part in determining the extraction rate, but the dominance of one factor over the other can lead to short cuts in the optimization process. If diffusion is limiting (hot ball model), then greater swelling and higher temperatures will accelerate extraction. Increasing the flow rate or solubility will not help. In the case of solubility-limited extraction, greater swelling of the polymer will not help, and raising the temperature is likely to slow down SFE as the density of the solvent diminishes.

There are different methods for identifying the limiting factor in an extraction. A plot of $\ln(m/m_0)$ may show the classic 'hot ball' shape, indicating significant diffusion control (Figure 1(A)). If the line is straight, intersecting the origin, then this indicates solubility-limited behaviour (Figure 1(C)). A problem with these methods is that nonspherical particles, nonuniform initial distribution of analyte in the particle or a mixture of particle sizes can easily distort the shape of the curve. An alternative method is to measure extraction rates at different flow rates. If the extraction is diffusion-limited, then increasing the flow rate will have little effect. However, increasing the flow rate of a solubility-limited extraction will increase the extraction rate. Figure 2 shows concentration profiles during extraction for different values of solubility.

Effect of CO₂ on Polymers

CO₂ dissolves in polymers, swelling, softening and plasticizing them. Material will diffuse much faster through the swollen polymer, and diffusion rates can be increased by several orders of magnitude. The T_g and softening points are also lowered. The extent of this lowering depends on the pressure and the nature of the polymer. CO₂ is mainly soluble in the amorphous part of a polymer, so the greater the amorphous content, the larger the effect of the CO₂. Increasing the pressure also causes more CO₂ to enter the polymer. The result is a complex interaction, with CO₂ lowering T_g , which increases the amorphous content, allowing more CO₂ to enter. This means that the softening point is not easy to predict from the usual softening point. In most cases, higher pressure of CO₂ will increase extraction rates in SFE from polymers, as this will enhance both solubility and diffusion, by increased swelling of the polymer. For highly amorphous or rubbery polymers, a maximum can be reached in the extraction rate with increasing pressure. This is because the softening point is lowered by the extra CO₂ dissolving in the polymer as the pressure increases. If it is lowered below the extraction temperature, the particles will agglomerate and slow the extraction. In these cases careful optimization of pressure and temperature is required for maximum extraction rates. Addition of a solvent as a modifier to the CO₂ can also swell the polymer, as well as increase the solubility of the analytes. A solvent known to swell the polymer at room temperature will have the greatest swelling effect.

SFE from Polymers

As indicated above, the optimization of SFE from polymers is not straightforward. Generally, the

optimum conditions are likely to be at as high a temperature as possible, just below that at which the polymer melts, with as high a pressure of CO₂ as possible. The addition of a small amount (10%) of a cosolvent or modifier which is known to swell the solvent will accelerate extraction. There are many examples of polymer extractions with SFE, and extraction times are usually much shorter than conventional extraction times.

Pressurized Fluid Extraction

PFE is similar to SFE. The sample is held in a cell and the solvent is passed over it at elevated temperature and pressure. The commercial Accelerated Solvent Extraction (ASETM) is a trademark of Dionex Corp., and uses static extraction. Modified SFE equipment has also been used, and can use static or dynamic extraction. The solubility of polymer additives in liquid solvents at the high temperatures used in PFE is likely to be high enough that extractions are largely diffusion-limited. This is illustrated in Figure 3 for the extraction of Irganox 1010 from polypropylene. The curve has been fitted assuming ba is infinite, i.e. completely diffusion limited (hot ball model). The fit is reasonably good, indicating that the assumption is valid. Pressure has much less effect on liquids than supercritical fluids. Liquids are almost incompressible, and therefore the pressure applied only has the effect of keeping the solvent liquid above its atmospheric boiling point.

The most difficult part of method development for PFE of polymers is selecting the solvent. Solvents used for atmospheric pressure extractions have usually been selected to swell the polymer, hence speeding up the extraction. However, when these solvents are used at high temperatures, the polymer dissolves. As the solvent cools in the transfer lines of the equipment, the polymer drops out of solution, causing blockages. Partially dissolved or melted polymer also agglomerates, increasing particle size and slowing down extraction rates. Solvents conventionally used for polymer extractions therefore cannot be used for PFE. The interaction between the solvent and polymer can be considered as a continuum, from no interaction (no swelling) through increasing swelling until eventually dissolution occurs which can be thought of as infinite swelling. The degree of interaction generally increases with temperature for a given solvent, and therefore, a solvent will just dissolve a polymer at a particular temperature, called the 'theta temperature'. We can assume that the extent of swelling is similar for each solvent at just below the theta temperature. The criteria for the best PFE extractions from polymers are

Figure 3 Extraction of Irganox 1010 from polypropylene by PFE. Symbols = experimental results, solid lines = fitted curve using the 'hot ball' model. (Reproduced with permission from Vandenburg, Clifford, Bartle *et al.* (1998) *Analytical Chemistry*, 70: 1943–1948).

as follows:

1. The temperature should be as high as possible to make D as large as possible. For a given 'openness' of the polymer structure, the higher the temperature, the faster the extraction. There will be an upper limit to the temperature, set either by the melting point of the polymer or the stability of the extracted analyte, which we can call T_{\max} .
2. The polymer structure should be as 'open' as possible. This effectively means that the polymer should be swelled as much as possible without dissolution or agglomeration of particles.

By combining the requirements of 1 and 2 above, what is required from the best extraction solvent is that the theta temperature is just above T_{\max} . The diffusion will then be maximized through both the highest temperature possible and the most open polymer structure. No other combination will give faster extraction.

Solvent Selection

Hildebrand Solubility Parameter

How can we select the best solvent? The use of solubility parameters is a good starting point. The Hildebrand solubility parameter is defined as the internal energy of vaporization divided by the molar volume. It is also called the cohesive energy density, and gives an indication of how strongly the material is held together. The principle of 'like dissolves like' applies, and solvents will dissolve polymers with a similar

solubility parameter. The theta temperature tends to be higher the greater the difference in solubility parameter between solvent and solute. There are several more sophisticated measures of solubility in polymers, which take into account polar and hydrogen bonding interactions, but are not as simple as the Hildebrand parameter, which sums up the solubility behaviour as a single number. Hildebrand parameters are also widely available for polymers and solvents. Examples of common solvents and polymers is given in Table 1. However, the simplicity of the parameter also means that exact numeric accuracy is sometimes lost, and specific numerical predictions are difficult to make from this parameter alone.

Table 1 Solubility parameters of selected solvents and polymers

Material	Solubility parameter ($\text{MPa}^{1/2}$)
Hexane	14.9
Cyclohexane	16.8
Ethyl acetate	18.6
Chloroform	19.0
Dichloromethane	19.8
Acetone	20.3
2-Propanol	23.8
Ethanol	26.0
Methanol	29.7
Polypropylene	16.6
PVC	19.5
PET	20.5
Nylon 66	28
PMMA	19.0

Use of Binary Mixtures

A suggested scheme for PFE solvent selection is to use the solubility parameter as a guide for initial solvent selection of a binary mixture. The exact proportions of the solvents can then be determined with a few simple experiments. The two solvents should be a 'good' solvent, which has a solubility parameter close to that of the polymer, and a 'poor' solvent, with a solubility parameter distant from the polymer. Initially, T_{\max} is determined by extracting with pure poor solvent for a set time at increasing temperatures. Initially, the amount extracted will increase with temperature as swelling and diffusion rate are increased. Eventually a maximum will be reached, representing either the melting of the polymer or the decomposition of the analyte. The maximum swelling at this temperature is then determined by a series of extractions with increasing amounts of the good solvent, again until a maximum is reached when the polymer begins to dissolve and agglomerate. If required, the proportions and temperature can be fine tuned to further maximize extraction rates. Often the initial values will be sufficient, and further marginal improvements not worth the extra effort. Once these conditions are identified, the time for the extraction can be determined by a series of extractions on the same sample until no further analyte is detected.

Examples of the best solvent mixtures suggested to date for some polymers are indicated in Table 2.

An advantage of this system of selection is that the solvents can be selected from any with a close and distant solubility parameter. The criteria may be cost, environmental considerations or simply those easily available. Equally good extractions could be obtained from a variety of different solvent mixtures. The extraction time for ground polymers is likely to be minutes rather than hours. Using the conditions in Table 2, the extraction times for polypropylene, nylon and PVC were all under 20 min. This is much faster than extractions using conventional extraction techniques.

Microwave Assisted Extraction

MAE can be either 'open focused', where the vessel is at atmospheric pressure, or 'closed vessel', where the solvent is kept liquid above the usual boiling point in a sealed, pressure resistant vessel. The effects of microwaves on extraction can be either purely thermal or through some other interaction of the microwaves with the matrix or analyte. For extraction from polymers, nonthermal effects have not yet been satisfactorily demonstrated, and the benefits for extraction may be primarily thermal. There are two components to the enhanced extraction rates for MAE:

1. Microwaves heat the solvent directly, resulting in much faster heating than conventional oven heating.
2. The closed pressure vessels allow heating above the atmospheric pressure boiling point of the solvent.

In MAE the extraction is always static. The solvent and polymer are placed in a vessel and heated by microwaves. The analyte dissolves in the solvent. Typical vessel sizes are 100 mL (e.g. MES 1000 by CEM Corp., USA).

In order to be heated by microwaves, the solvent must have a significant dielectric constant (relative permittivity). Some examples for common solvents and their dielectric constant are given in Table 3.

Optimization of extraction conditions with MAE is similar to that in PFE. Solvents and temperatures which are effective for PFE are also likely to be good for MAE, and extraction conditions can be worked out in a similar way. An extra requirement is that a major component of the solvent must have a significant dielectric constant, which does restrict the choice of solvents.

An alternative possible with MAE is the dissolution/precipitation approach. MAE does not have the problems of blocked transfer lines associated with PFE, and therefore it is not a problem if the polymer dissolves. The issue is whether the dissolution occurs faster than the extraction without dissolution. If the particles of polymer can be prevented from softening

Table 2 Suggested extraction conditions for PFE from some polymers

<i>Polymer</i>	<i>Poor solvent (%)</i>	<i>Strong solvent (%)</i>	<i>Extraction temperature (°C)</i>
Polypropylene	Propan-2-ol (97.5)	Cyclohexane (2.5)	140
PVC (plasticized with di-octylphthalate)	Hexane (60)	Ethyl acetate (40)	170
PET	Ethyl acetate (100)		190
Nylon 66	Hexane (60)	Ethanol (40)	170
PMMA	Hexane (70)	Ethyl acetate (30)	150

Table 3 Dielectric constant of solvents at 25°C

Solvent	Dielectric constant
Water	78
Nitrobenzene	35
Methanol	33
Ethanol	24
Ammonia	17
Hydrogen sulfide	9 (at – 85°C)
Benzene	2
Carbon tetrachloride	2
Cyclohexane	2

and agglomerating before dissolving, then it is likely that the dissolution will be fast. This is an area which requires further investigation.

MAE extractions of polymers have not been reported as much as SFE and PFE extractions, but those that have indicate very rapid extractions. In some cases, the most time-consuming part is the cooling of the vessels before opening. The advantages over PFE are more rapid heating and no possibility of blocking the transfer lines. The disadvantages are a more limited choice of solvents and longer cooling down times. SFE, PFE and MAE offer distinct advantages over conventional extraction methods, but at higher initial cost. The particular method chosen will depend on the exact requirements for extractions in the individual laboratory.

POLYSACCHARIDES

Centrifugation

S. E. Harding, University of Nottingham, Leicestershire, UK

Copyright © 2000 Academic Press

Polysaccharides are, as their name implies, polymers of saccharide residues. The general formula of saccharide or carbohydrate residues is often quoted as $(\text{CH}_2\text{O})_n$, although this is an oversimplification which needs to be modified in many cases to take into account, e.g. amino, sulfate and phosphate groups. Most saccharide residues are five or six membered

ring structures with one member of the ring being oxygen.

Polysaccharides are becoming increasingly important in biomedical, pharmaceutical food and health products. The role of preparative centrifugation in polysaccharide development has not been significant compared to other classes of compounds such as nucleic acid and proteins. In part, this may be due to the considerable heterogeneity of polysaccharides, and techniques such as chromatography and precipitation-based methods have been more commonly applied. However, *analytical* centrifugation techniques are becoming increasingly used as a means of characterizing the size and shape of polysaccharides in solution as well as for investigating their interaction with each other and with other biopolymers such as pro-

teins. Analytical centrifugation is also being used as an alternative to rheological methods for investigating the structure of polysaccharide gels. Analytical centrifugation is well suited for the analysis of polydisperse materials and (apart from density gradient methods) does not involve another separation medium.

The aim of this article is threefold:

1. to survey briefly the types of information that can be obtained about polysaccharide systems by analytical centrifugation;
2. to describe those aspects of the equipment that are of particular relevance for obtaining this information;
3. to describe the types of experiments used to obtain this information.

The centrifugation methods applied to macromolecules are termed *ultracentrifugation*, because of the high rotor speeds (up to 60 000 rpm) required to produce sedimentation or a measurable concentration redistribution. At these high speeds the rotor needs to be in a vacuum chamber to avoid friction-heating effects. An analytical ultracentrifuge is an ultracentrifuge equipped with a special optical system for monitoring the sedimentation process.

Despite the fact that Svedberg, who won the Nobel Prize in 1926 for inventing the analytical ultracentrifuge, and his PhD student Gralen both conducted extensive work on the ultracentrifugation of polysaccharides, it is only relatively recently that the technique has been more widely utilized for the study of these substances.

Measurable Parameters

Molecular Weights and Heterogeneity

One of the most fundamental pieces of information describing a macromolecule is its molecular weight, M . M values for polypeptides can usually be evaluated without difficulty from chemical sequence information. For polysaccharides this is not the case, primarily because of their heterogeneity due to polydispersity and also, in some cases, self-association phenomena. An average molecular weight, usually the weight average, M_w , is normally specified. M_w is usually available to better than $\pm 10\%$ from sedimentation equilibrium in the ultracentrifuge, and M_z to somewhat less precision depending on the optical detection system employed. In some circumstances M_n can also be measured, although osmotic pressure is a more appropriate technique. The ratios of the z average molecular weight, M_z to M_w or M_w to the number-average, M_n are used as indices for poly-

dispersity, popular with commercial manufacturers of polysaccharides as a measure of the narrowness of a molecular weight distribution.

Direct molecular weight distributions are more difficult to obtain with centrifugation procedures and depend on assumed models (Gaussian, log-normal etc.): nowadays size exclusion chromatography systems coupled online to multi-angle light-scattering systems, or SEC-MALLS are much more common, but the ultracentrifuge still provides a valuable check on the M_w or M_z .

A good indication of chemical heterogeneity (e.g. purity) of a saccharide system can be provided by analytical isopycnic density gradient ultracentrifugation.

Molecular Shape or Gross Conformation

In general two levels of information are sought:

1. Delineation between the conformation type or zone of a polysaccharide, as represented by the Zonal diagram of **Figure 1**: extra rigid rod, rigid rod, semi-flexible coil, random coil and globular/highly branched.
2. Having established the conformation type, more quantitative information can be sought. For example, for approximately rigid structures this can be given in terms of the triaxial dimensions or shape of the molecule: for more flexible chain-like structures the chain diameter, d , contour length L and the flexibility can be described in terms of the persistence length, L_p (**Figure 2**).

Water Binding or Hydration

The sedimentation coefficient from sedimentation velocity experiments in the ultracentrifuge depends not only on molecular conformation but also the extent of solvent binding (chemical interactions via, for example, hydrogen bonds or just physical entrainment). Water binding is an important functional property of polysaccharides (for example, in foods, or as hydrogel drug delivery forms). Unfortunately, the conformation has to be known or assumed to obtain the extent of swelling through water binding: conversely, assumptions of water binding extent are often required to obtain quantitative conformation information.

Analytical Ultracentrifuges and Polysaccharides

Analytical ultracentrifuges have already been described by Lewis elsewhere in this encyclopedia. The traditional ultracentrifuges, such as the classical Model E analytical ultracentrifuge from Beckman

Figure 1 Conformation zoning of polysaccharides: (A) extra rigid rod; (B) rigid rod; (C) semi-flexible coil; (D) random coil; (E) globular or highly branched. (Reproduced from Pavlov GM, Rowe AJ and Harding SE (1997) Conformation zoning of large molecules using the analytical ultracentrifuge. *Trends in Analytical Chemistry* 16: 401, with permission from Elsevier Science.)

Instruments (Palo Alto, USA), have now largely been replaced by the new generation Optima XL-A and XL-I, also from Beckman. Both have full online computer data capture and analysis facilities.

Optima XL-A Ultracentrifuge

This model appeared in *c.* 1990 and is equipped with a UV/visible absorption optical detection system. Unfortunately, polysaccharides are generally transparent in the visible and also, unlike proteins and nucleic acids, in the near UV (wavelength $\lambda > 240$ nm). In the far UV (200–220 nm), they absorb and can therefore

in principle be detected. Unfortunately other materials such as buffer salts also absorb strongly in this region and hence for many applications an absorbing chromophore must be attached to the polysaccharide. Some success has been achieved with this latter approach, although possible alterations to the structure and molecular weight (e.g. a state of self-association) caused by the incorporation of the chromophore can result in measurement errors. Other polysaccharides, such as xylans and pectins, have some inherent absorbance at ~ 240 – 260 nm and this can be taken advantage of.

Optima XL-I Ultracentrifuge

This model appeared in *c.* 1996 and, in addition to the UV/visible absorption optics of the XL-A, has a refractometric optical system known as Rayleigh interference optics. This optical system can be applied to proteins, nucleic acids and polysaccharides. One drawback for sedimentation equilibrium (molecular weight) work is that, because of the upper limit of ~ 12 mm of the optical path length of the centrifuge cell, the lower limit for the concentration of the polysaccharide solution loaded into the cell is ~ 0.8 mg mL⁻¹. This is a major limitation for polysaccharides since low concentrations are necessary to minimize the effects of the large thermodynamic nonideality of these substances, compared to proteins.

Model E Ultracentrifuge

These have not been commercially available for 20 years but there are a number still in active use, although only a few are being applied to the study of polysaccharides. Besides Rayleigh interference, they also have another type of optical system, not current-

Figure 2 More detailed conformation representations of polysaccharides in solution: length and flexibility parameters for a linear polysaccharide: L , Contour length; L_p , persistence length, defined as the projection length along the initial direction of chain of length L and in the limit of $L \rightarrow$ infinity. (Reproduced with permission from Tombs and Harding 1998.)

ly available on the Optima machines, the Schlieren or refractive index gradient system, permitting high concentrations and facilitating gel work. For molecular weight analysis, Rayleigh optics give primarily M_w , whereas Schlieren optics yield M_z . Thus the model E is ideal for obtaining polydispersity indices (M_z/M_w , see above). However, because of the lack of availability of this instrument, people requiring this type of measurement need to consult the handful of laboratories still running these instruments.

Types of Ultracentrifuge Experiment for Polysaccharide Analysis

The principal types of measurement using the analytical ultracentrifuge on solutions of polysaccharide are:

- Sedimentation equilibrium: for obtaining the weight average molecular weight, M_w , and the z average molecular weight, M_z . Molecular weights are conventionally expressed in daltons or in molar mass units (g mol^{-1}). The thermodynamic second virial coefficient, B ($\text{mL mol}^{-1} \text{g}^{-2}$) can also be measured.
- Sedimentation velocity: for obtaining the sedimentation coefficient, s (measured in seconds (s) or svedbergs (S), where $1 \text{ S} = 10^{-13} \text{ s}$) and the concentration dependence or Gralen parameter k_s (mL g^{-1}) of the sedimentation coefficient. Both s and k_s can be used to obtain conformation, water binding and molecular weight information.
- Boundary spreading experiments: for obtaining the translational diffusion coefficient, D ($\text{cm}^2 \text{s}^{-1}$) and its concentration dependence parameter, k_D (mL g^{-1}). The polydispersity of polysaccharides is however a major complicating factor.
- Analytical isopycnic density gradient ultracentrifugation: primarily used for assaying the purity of a polysaccharide preparation on the basis of density.

In addition, sedimentation velocity and equilibrium can be used to probe the structure of gels, primarily through measurement of the swelling pressure of the gel, and also the mobility/diffusion of molecules through gels or incompatible mixed-phase systems.

Sedimentation Equilibrium of Polysaccharide Solutions

In this method the ultracentrifuge is spun at a speed sufficiently low (for example, $\sim 10\,000$ rpm for a pectin polysaccharide of $M_w \sim 200$ kDa) that the centrifugal force is comparable to the back-force due to diffusion. The distribution of the polysaccharide in the centrifuge cell is recorded using Rayleigh optics

and equilibrium is typically established between 24 and 48 h. Attainment of equilibrium is assessed by comparing optical records taken at 4–8 h intervals. The time required to attain equilibrium depends on the polysaccharide and the length of solution column in the centrifuge cell: a 3 mm column requires ~ 0.1 mL for a 12 mm optical path length cell (XL-I or Model E) or ~ 0.25 mL for a 30 mm cell (Model E only). Shorter columns take less time but yield less precise information. The length of time of an experiment can be compensated for by running samples in multiples using multi-hole centrifuge rotors and/or multi-channel centrifuge cells.

Molecular Weight Determination

The simplest interpretation of the optical records from a sedimentation equilibrium experiment is obtained from the average slope of a plot of the log of the concentration, $C(r)$ in the cell versus the square of the radial displacement, r , from the rotor centre: such a slope yields the apparent weight-average molecular weight, $M_{w,app}$. In evaluating the average slope, care must be taken to include as much of the distribution in the centrifuge cell as possible (from meniscus to cell base). Fortunately, software (MSTAR) is available to assist with this task. Rayleigh optics only record concentration of solute relative to the meniscus, thus requiring the concentration at the meniscus to be determined in order to convert relative concentrations to $C(r)$. After these factors have been taken into account, extrapolation of $1/M_{w,app}$ to $C = 0$ (where C is the cell loading concentration) yields the reciprocal of the weight average M_w from the intercept and, also the second thermodynamic virial coefficient, B , or as an alternative notation A_2 from the limiting slope. (This term also appears in osmotic pressure or static light-scattering measurements.) Correct to first order in concentration, this extrapolation is described by:

$$1/M_{w,app} = (1/M_w) \cdot (1 + 2BM_w C) \quad [1]$$

Herein lies a difference between proteins and polysaccharides. The nonideality term $2BM_w C$, which can often be neglected at low concentration for proteins, is usually significant even at low concentration for polysaccharides because of their much greater nonideality: indeed, the term $1 + 2BM_w C$ represents the factor by which measurement of $M_{w,app}$ at a finite concentration C underestimates the true molecular weight (Table 1). This nonideality derives from the large exclusion volumes of these substances and from the fact that many are polyelectrolytes (highly negatively charged, such as pectins, alginates, xanthan, carrageenan, or highly positively charged, such as chitosans). However, although these polyelectrolyte

Table 1 Comparative molecular weights and nonidealities of polysaccharides from sedimentation equilibrium measurements

	$10^{-6} \times M_w$ ($g\ mol^{-1}$)	$10^4 \times B$ ($mL\ mol^{-1}\ g^{-2}$)	BM_w ($mL\ g^{-1}$)	$1 + 2BM_wC^a$

Alginate	0.35	29.0	1015	1.406

^aBased on the lowest possible loading concentration ($\sim 0.2\ mg\ mL^{-1}$ in a cell with a 30 mm path length centrepiece).

effects can be largely suppressed by the inclusion of a low molecular weight electrolyte to increase the ionic strength of the solution, eqn [1] is usually only valid for dilute solutions of polysaccharides and at higher concentrations, extra terms (in C^2 or C^3) are necessary. In such cases direct nonlinear, extrapolation of $M_{w,app}$ to $C = 0$ usually gives a better estimate of M_w than the reciprocal ($1/M_{w,app}$) extrapolation procedures. The other big difference between proteins and polysaccharides is that the latter are usually very polydisperse.

It is also possible from a single experiment to obtain local or point average $M_{w,app}(r)$ at radial positions r , as a function of $C(r)$. Extrapolation of $M_{w,app}(r)$ to $C(r) = 0$ provides a further estimate for M_w , although because of redistribution of solute in the centrifuge cell this can yield and underestimate for M_w . From further manipulations, including concentration extrapolations to the radial positions of the solution meniscus and bottom of the centrifuge cell, the (apparent) z average molecular weight $M_{z,app}$ can be obtained. Similar corrections to $C = 0$ are required to obtain M_z (although the factor in eqn [1] is 4, not 2). A more precise estimate for $M_{z,app}$ can be obtained if Schlieren optics are used instead of Rayleigh optics: this is because Schlieren optics record the concentration gradient, $dC(r)/dr$ (as opposed to $C(r)$) versus radial displacement, r .

In cases where there may be reversible self-association phenomena, the B term in eqn [1] must be modified to incorporate an association term.

Sedimentation Velocity of Polysaccharide Solutions

At higher speeds than used for sedimentation equilibrium, sedimentation forces become well in excess

of diffusion forces and a macromolecular species will sediment. The sedimentation coefficient, s , of a macromolecular component is its sedimentation rate per unit centrifugal field. It will be a function of the size, shape and degree of water association or hydration of the biopolymer. Like the apparent molecular weight, $M_{w,app}$, it will be affected by the nonideality of the system, and will need correcting for these effects by measuring at a series of concentrations and extrapolating to zero concentration to yield the ideal or infinite dilution value s^0 . For polysaccharides this is best accomplished with a reciprocal plot:

$$1/s_{20,w} = (1/s_{20,w}^0) \cdot (1 + k_s C) \quad [2]$$

where C is the sedimenting concentration and k_s is the concentration dependence or Gralen parameter. The subscripts 20,w mean that, by convention, sedimentation coefficients measured at a given temperature are corrected using simple formulae to standard conditions of solvent viscosity and density: that of water at 20°C.

As with eqn [1] for M_w , eqn [2] for $s_{20,w}^0$ is generally only applicable for dilute solutions of polysaccharides: for higher concentrations, and even for dilute solutions of certain extremely nonideal polysaccharides like alginate and xanthan, higher order terms in C are needed to describe adequately the concentration dependence. As with M_w , where such higher terms are necessary, direct extrapolation of $s_{20,w}$ to $C = 0$ rather than $1/s_{20,w}$ is generally a more reliable procedure for estimating $s_{20,w}^0$. Both $s_{20,w}^0$ and k_s can be used for conformation and hydration analysis, and also as a less direct alternative to sedimentation equilibrium for molecular weight estimation.

Besides the use of higher rotor speeds (for example, $\sim 50\ 000\ rpm$ for a pectin polysaccharide of $s_{20,w}^0 \sim 2\ S$), longer solution column lengths are gener-

ally used (~ 1 cm corresponding to ~ 0.4 mL of solution in a 12 mm path length Optima XL-I centrifuge cell), compared with sedimentation equilibrium experiments.

General Conformation Analysis of Polysaccharides

The Wales-van Holde ratio A useful guide to the gross conformation is the Wales-van Holde ratio. The Wales-van Holde ratio is defined as the ratio of the Gralen parameter k_s to the intrinsic viscosity $[\eta]$. The intrinsic viscosity can be measured relatively simply by viscometric or rheological methods, and both parameters are expressed in units of mL g^{-1} . It is known that this ratio has values of about 1.6 for random coils and spherical conformations and reduces to a limiting value of approximately 0.2 for rigid rod-shaped molecules. A proviso for the use of k_s in this way is that, for highly charged macromolecules, charge effects must be suppressed by using (aqueous) solvents of sufficient ionic strength (Table 2).

The Mark-Houwink-Kuhn-Sakurada Representation The Wales-van Holde ratio can be used to distinguish rods from either spheroidal or random coil conformations but cannot be used to distinguish between the latter two. However, advantage can be taken of the polydispersity of polysaccharides in that if the sedimentation coefficient and molecular weights are measured for a series of fractions (separated by column chromatographic procedures) of a polysaccharide preparation, then the exponent in the relation between $s_{20,w}^0$ and M weight or volume-average can be used to distinguish random coils from rods and spheroidal conformation types:

$$s_{20,w}^0 = K'' M^b \quad [3]$$

Table 2 Values of the Wales-van Holde ratio $k_s/[\eta]$ and the Mark-Houwink-Kuhn-Sakurada b coefficient for some polysaccharides

	$k_s/[\eta]$	b	Conformation
Dextran fractions		0.44	Random coil
DIT-dextran		0.56	Semi-flexible coil
Pullulans	1.4	0.45	Random coil
Yeast mannan	1.3	0.43	Random coil
β -glucans	0.4		Extended
Alginates	0.6		Extended
Pectins (low methoxy)	0.2	0.17	Rigid rod
Xanthan (keltrol)	0.28		Rigid rod
Amylopectin*	1.45		Spheroidal/heavily branched

DIT, di-iodotyrosine dextran. All in aqueous solvent except* (90% dimethyl sulfoxide).

Eqn [3] is known as a Mark-Houwink-Kuhn-Sakurada (MHKS) or just Mark-Houwink relation. Other MHKS relations exist between intrinsic viscosity and M (exponent a or α), radius of gyration and M (exponent c or ν) and the diffusion coefficient and M (exponent $-e$). The exponent b (sometimes given as $1-b$), measured from double logarithmic plots of $s_{20,w}^0$ versus M , has characteristic values depending on the conformation type: these are 0.67, 0.4–0.5 and 0.15 for spheres, random coils and rigid/extra rigid rods respectively (Table 2).

If K'' and b have been measured for a series of polysaccharide fractions, the molecular weights of subsequent preparations of that polysaccharide can then be estimated from measurement of $s_{20,w}^0$.

Conformation zoning from combination of $s_{20,w}^0$, k_s and the mass per unit length An even better guide to the overall conformation type or zone (Figure 1) can be obtained by combining $s_{20,w}^0$, k_s and the mass per unit length, M_L . The latter parameter must be measured using a separate technique, but a number of M_L values for polysaccharides have been published on the basis of electron microscopy or X-ray diffraction studies. The concept of zoning in this manner was conceived in terms of empirical data of polysaccharides of known conformation (Figure 3A), supported by the theoretically known limits for spheres and extra-rigid rods, to produce the characteristic diagnostic plot of Figure 3B.

For a polysaccharide whose conformation type or zone is unknown, from measurement of $s_{20,w}^0$ and k_s from a sedimentation velocity experiment and knowledge of, or an assumption concerning, M_L , the conformation zone can be read directly from Figure 3B.

More Detailed Conformation Analysis of Polysaccharides

Once the conformation type or zone has been established, more detailed information about conformation can be sought. It is worth stressing that, because of the inherent polydispersity of polysaccharides, much of the information obtained can only represent average properties: claims of parameter measurements to a high precision should be treated with some caution.

$s_{20,w}^0$ - M relations: worm-like coil modelling The simple MHKS dependence of $s_{20,w}^0$ on M described above has been extended for linear polymers (zone A–D molecules of Figure 1), including DNA and polysaccharides to include terms containing the mass per unit length M_L (or molecular weight M and the

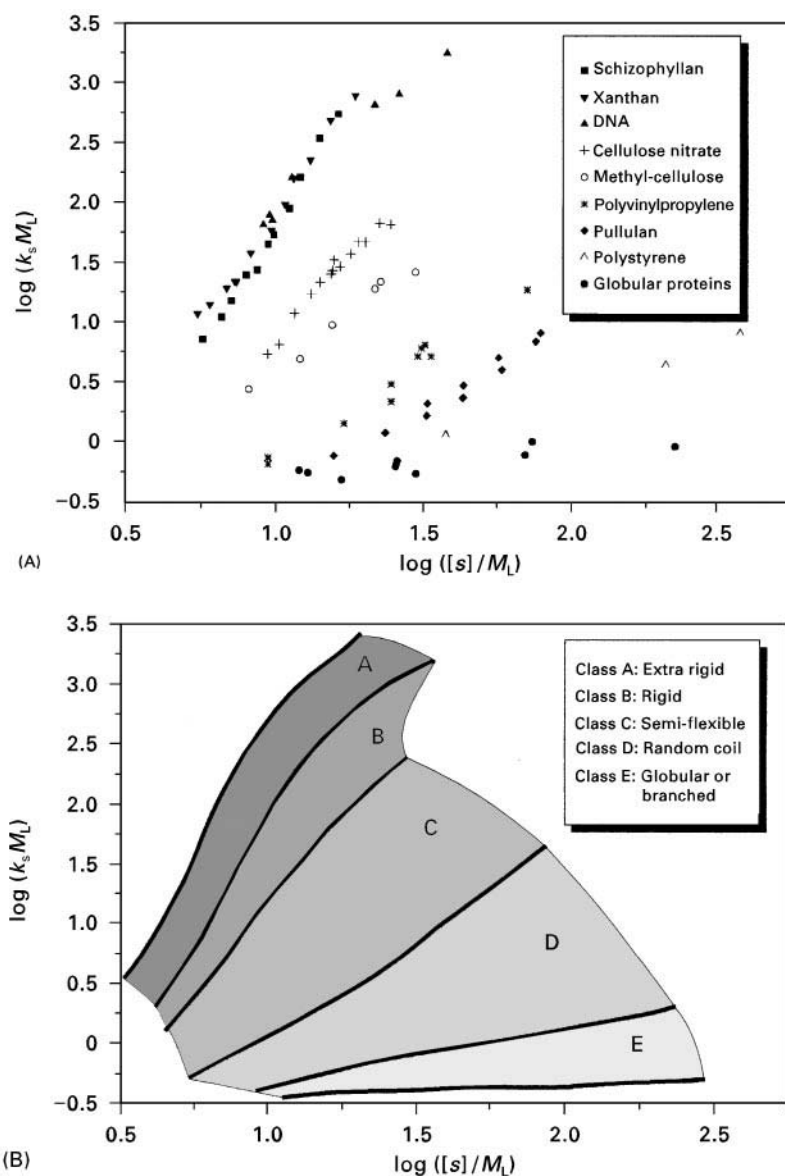

Figure 3 Sedimentation conformation zoning of polysaccharides. (A) Dependence of $\log(k_s M_L)$ versus $\log [s]/M_L$ for 82 macromolecules of known conformation type. (B) Corresponding diagnostic plot: for a measured $[s]$, k_s and M_L , the conformation of a given polysaccharide can be zoned. $[s] = s_{20,w}^0 \eta_0 / (1 - \bar{v} \rho_0)$ where η_0 and ρ_0 are the viscosity of water at 20°C and \bar{v} the partial specific volume. $[s]$ can also be defined for other solvents, although k_s must then correspond to that solvent. (Reproduced from Pavlov GM, Rowe AJ and Harding SE (1997) Conformation zoning of large molecules using the analytical ultracentrifuge. *Trends in Analytical Chemistry* 16: 401, with permission from Elsevier Science.)

contour length, L), the chain diameter, d , and the persistence length, L_p . As with MHKS, worm-like coil modelling has not only been worked out for the sedimentation coefficient, but also for other hydrodynamic parameters.

The Wales–van Holde ratio, $k_s/[\eta]$, for rigid structures It has already been noted how this ratio can help to distinguish rod-shape polysaccharides from the more randomly coiled and spheroidal materials.

For approximately rigid structures, more precise information about the molecular conformation, in terms of average ellipsoidal axial ratios, can be obtained without the complication of having to take into account molecular hydration, since this is essentially eliminated in the ratio. Detailed relations are available between $k_s/[\eta]$ (referred to for simplicity by the parameter R) and the axial ratio for ellipsoids of revolution, or the two axial ratios for general triaxial ellipsoids. We stress the phrase approximately rigid

structures. For polysaccharides this procedure would not be applicable to flexible coils, but may be applicable to rod-shaped or highly branched structures (zones A, B or E molecules of Figure 1): k_s has however been mainly applied in this way to protein systems, and not polysaccharides.

$s_{20,w}^0$ and the frictional ratio In addition to $k_s/[\eta]$, the sedimentation coefficient $s_{20,w}^0$ can also be used directly to extract the axial ratios of a quasi-rigid structure. Knowledge of $s_{20,w}^0$, together with the molecular weight and other parameters (density ρ_0 and viscosity η_0 of water at 20.0°C) yields the particle frictional parameter known as the translational frictional ratio f/f_0 . This in turn can be related to a shape parameter known as the Perrin function, P , and swelling ratio, S_w , defined as the ratio of the volume of a macromolecule swollen through hydration to that of the anhydrous macromolecule:

$$f/f_0 = P \cdot S_w^{1/3} \quad [4]$$

Thus, if S_w is known or assumed, the shape parameter P can be found and from this the axial ratios from rigorous hydrodynamic relations. Besides complications through molecular flexibility, the stumbling block is S_w . Whereas for proteins, S_w will be moderate (~ 1 – 2) and predictable to a certain degree, for polysaccharides this will not be so. In fact, eqn [4] is more useful from a polysaccharide context for predicting S_w , since, despite the presence of the cube root term, f/f_0 is still essentially a more sensitive function of swelling than shape.

Measurement of Water Binding or Swelling Ratios S_w

It has been shown how measurement of the frictional ratio (via $s_{20,w}^0$) can be used to estimate S_w , the swelling ratio. For a rigid structure, if the shape is established from measurement of $k_s/[\eta]$, then P can be defined and hence S_w found from eqn [4].

For more general structures, another route that has been suggested, applicable to both rigid and flexible structures, is to use the ratio of the concentration dependence term for viscosity (k_η) to k_s :

$$S_w \sim k_\eta/k_s \quad [5]$$

k_η (mL g⁻¹) comes from the analogous relation of eqn [2] for viscosity:

$$\eta_{\text{red}} = [\eta](1 + k_\eta \cdot C)$$

where η_{red} (mL g⁻¹) is the reduced viscosity at concentration C .

Diffusion Measurements

One of the classical ways of measuring translational diffusion coefficients, D , is to use the optical system on the ultracentrifuge to follow the time-dependent spreading of a layered boundary between a macromolecular solution and its solvent: if a rotor speed is employed, large enough to stabilize the system but low enough so as to minimize appreciable sedimentation, measurement of boundary height and width changes with time can be used to measure D . The diffusion coefficient itself can be corrected to standard conditions of temperature and solvent viscosity (water at 20.0°C) to give $D_{20,w}$, and extrapolated to zero concentration to give $D_{20,w}^0$ and the concentration dependence parameter k_d (mL g⁻¹). $D_{20,w}^0$ combined with $s_{20,w}^0$ in the Svedberg equation can be used to estimate the molecular weight. Alternatively $D_{20,w}^0$ provides a different route to $s_{20,w}^0$ for obtaining the frictional ratio f/f_0 .

Although measurement of $D_{20,w}^0$ in this way is highly reliable for many protein systems, there are problems with polysaccharides, again deriving from polydispersity: indeed, this application of the ultracentrifuge has now largely been superseded by dynamic light-scattering methodology.

Analytical Density Gradient Centrifugation

Density Gradient Sedimentation Equilibrium

By dispersing the polysaccharides in a dense salt solution, a density gradient can be created in an ultracentrifuge cell. For a mixed macromolecular solute a particular macromolecular species will move or band at that region in the density gradient which corresponds to its own density: this procedure is known as density gradient or isopycnic (isodensity) sedimentation equilibrium. Normally, caesium salts are used to provide this gradient for polysaccharides. Since most polysaccharides have similar densities (or partial specific volumes), this is not very good for separating mixed polysaccharide systems, but is, however, useful for separating polysaccharides from glycoproteins or proteins. It has, for example, been recently used to assay the purity of xylans from other molecular contaminants. The method assumes no significant interaction between the caesium salts and the polysaccharide.

Density Gradient Sedimentation Velocity

A less dense solute may be used (e.g. sucrose) to retard the sedimentation rate in sedimentation velocity (enhancing resolution) as opposed to inducing banding in sedimentation equilibrium. The method

assumes no interaction between the solute and the macromolecule. However, since the sedimentation coefficients are usually very small (often between 1 and 2 S) – because of their large frictional ratios – and because of potential interactions with the separating medium, this method has not found major use for polysaccharide analysis or separation.

Polysaccharide Gels: Swelling Pressure

Sedimentation Equilibrium

If a gel is subjected to a centrifugal field, low enough to avoid sedimentation of the gel itself (typically < 10 000 rpm), a concentration gradient will be established as in a conventional sedimentation equilibrium experiment on a solution. The gradient indicates the locally dependent de-swelling of the gel, which is caused by the swelling pressure generated by the centrifugal field. The concentration gradient will depend on the structure of the gel (number and strength of the cross-links) and whether the gel is reversible or not.

Sedimentation Velocity

At sufficiently high rotor speed (> 10 000 rpm), the polymer concentration may drop to a sufficiently low level near the meniscus that a sol phase will appear: a conventional sedimentation velocity experiment can be performed, monitoring the movement of the boundary between gel and sol.

Data from sedimentation equilibrium and sedimentation velocity can be used to obtain the thermodynamic, elastic and structural parameters of the gel, complementing data from classical rheological approaches. Although gelatin has been the main focus of attention with this technique, several polysacchar-

ide gels have been successfully characterized, such as carrageenan, pectin and alginate.

Introduction

Separation, analysis and molecular weight distribution are very important for the characterization of polysaccharides in biochemistry, microbiology, agriculture and the food industry. During biosynthesis, a large range of components of different molecular

weight are formed. Gas chromatography (GC) can be used for the analysis of very complex polysaccharide mixtures whereas high performance liquid chromatography (HPLC) is preferred for simple polysaccharide mixtures and for purification.

High Performance Liquid Chromatography

HPLC was introduced into the field of carbohydrate chemistry for the separation of mono- to tetrasaccharides of neutral sugars found in natural products

Table 1 Pre-column derivatization of carbohydrates for use in HPLC

Reagent	Column	Mobile phase
2-Aminoacridone	C18 reverse or normal-phase	Ammonium acetate-acetonitrile

Dansyl hydrazine	C18 reversed-phase	Acetonitrile-water
Phenylisocyanate	C18 reversed-phase	Acetonitrile-phosphate buffer
Benzoyl chloride	Silica	Ethyl acetate-hexane
<i>o</i> -Phthalaldehyde	C18 reversed-phase	Acetonitrile-methanol-water

of interest to the food industry. However, more recent applications have included the analysis and purification of oligo- and polysaccharides containing neutral and acetamido sugars and sialylated, sulphated and phosphorylated oligosaccharides.

Several different HPLC packing materials and solvent systems have been investigated for carbohydrate separation including native and derivatized oligosaccharides chromatographed on bare silica, bonded silica (NH₂-silica), silica modified with soluble amines *in situ*, reversed phase (RP), anion- and cation-exchangers and size-exclusion chromatography (Table 1). In several instances, a combination of different chromatographic modes is required for the complete separation of all isomers present in mixtures of polysaccharides obtained from biological sources.

Experimental Approach

There are a number of different HPLC processes for separating carbohydrates that depend on different chemical and physical properties for resolution. These analyses can be divided into ion-exchange processes at high temperature ($\geq 60^\circ\text{C}$) and adsorption (partition) processes at lower (room) temperatures. The most commonly used ion-exchange process involves the separation of borate complexes on quaternary ammonium anion-exchange resins (Figure 1). Borate forms complexes with most carbohydrates. The stability of these is influenced by the spatial arrangement of the alcohol groups involved, *cis* hydroxyl groups forming the most stable compounds. The columns may be run isocratically using borate buffers or by the use of gradient or stepwise elution using borate buffers of increasing molarity or containing increasing salt concentrations. The resolution obtained with this process normally increases with increasing temperature as long as the ion-exchange resin is stable.

Polysaccharides may be separated in all these processes using aqueous acetonitrile solvents. The variation of elution times of all the components with the separation parameters (e.g. temperature, acetonitrile concentration, buffer pH) must be determined by computer analysis or by visual inspection of the curves. Microbial growth inhibitor should be present in all aqueous phases.

Techniques for Carbohydrate Chromatography

By using different approaches to synthesis, stationary phases for almost any known type of chromatographic interaction can be provided. Continuous porous polymer rods can, for example, be produced *in situ* by thermal or photopolymerization on suitable monomers. These stationary phases can be transformed to adapt them for ion exchange or hydrophobic interaction chromatography. A more specific interaction can be introduced by 'imprinting' the polymers during synthesis with the future analyte (enantioselective/affinity stationary phases). In a different approach, a sol-gel technique can be used to produce stationary phases on a silica basis. These phases are mechanically more stable and were, for instance, used to separate polyaromatic carbohydrates and sugars within minutes.

Figure 1 Analysis of an equimolar mixture of aldoses. A mixture of 15–60 nmol of L-rhamnose (Rha), D-lyxose (Lyx), D-ribose (Rib), D-mannose (Man), L-fucose (Fuc), L-arabinose (Ara), D-galactose (Gal), D-xylose (Xyl) and D-glucose (Glu) was dissolved in 100 μL of water and applied to a Hitachi No. 2633 resin column (8 mm i.d. \times 8 cm). The packing is a quaternary ammonium resin with an average bead diameter of 11 μm . The borate gradient (1 mL min⁻¹) was used to elute the carbohydrates using buffers A (0.25 mol L⁻¹, pH 8.2), B (0.4 mol L⁻¹, pH 7.4) and C (0.6 mol L⁻¹, pH 9.3). Post-column detection was by fluorimetry after reaction with 2-cyanoacetamide-borate. (Reproduced with permission from Chaplin MF and Kennedy JF (eds) (1994) *Carbohydrate Analysis: A Practical Approach*, 2nd edn, p. 17. Copyright IRL Press Limited.)

Adsorption chromatography Adsorption, or normal phase, chromatography relies on the surface hydroxyl groups of silica (and to a lesser extent alumina) which can interact with solutes and effect a separation on account of the different strengths of interaction. The separation of neutral oligosaccharides cannot be carried out conveniently by this method although limited separations can be achieved in water or by using aqueous-organic mixtures. The method is well suited to the analysis of derivatives of oligosaccharides of low degree of polymerization using non-aqueous eluents. The use of high concentrations of organic solvents in an aqueous eluent gives rise to problems of solubility of polysaccharides.

Bonded-phase chromatography By far the most frequently used systems for separation of oligosaccharides are those using chemically bonded phases that fractionate materials on the basis of their relative affinities for the mobile phase and the bonded phase. The two most important types of column are those containing the aminopropyl-bonded phase and a hybrid phase containing cyanopropyl- and aminopropylsiloxane-bonded ligands.

Separation of series of oligosaccharides from, for example, hydrolysed starch can readily be achieved with up to a degree of polymerization of 10 in 15–20 min using acetonitrile–water eluents containing 35–40% water (Figure 2). Increasing the water content to 45% can increase the number of detectable oligosaccharides up to about 15 units. However very high-molecular-weight materials cannot be analysed due to excessive retention and solubility problems in acetonitrile–water eluents. For a full analysis, separation by gel permeation or ion exchange is also required.

Instead of using a bonded silica aminopropylsiloxane-bonded phase, an alkyldiamine or polyalkylamine can be added to the eluent forming a dynamic equilibrium between an amine-containing phase coating the silica and that in the eluent. Separations are similar to those obtained using chemically bonded aminopropyl sorbents with separations of up to 20–25 units in 45 min with eluents containing 50% water in acetonitrile (Figure 3).

Ion-exchange chromatography Anion-exchange resins of styrene-divinylbenzene matrices in the sulfate form have been reported for the separation of the simple disaccharides using eluents of 80–90% ethanol in water. Rapid and efficient separation of simple and complex carbohydrates by high performance anion-exchange chromatography is obtained using a quarternized alkylamine sorbent made of

Figure 2 Separation of starch-derived oligosaccharides on a Spherisorb S5 NH₂ column (1, 2, 3, etc., refer to the degree of polymerization of the oligosaccharide). (Reproduced with permission from Chaplin MF and Kennedy JF (eds) (1994) *Carbohydrate Analysis: A Practical Approach*, 2nd edn, p. 48. Copyright IRL Press Limited.)

chemically modified nonporous and monodisperse highly cross-linked styrene copolymer particles having a diameter of 2.5 μm and a surface area of 3 $\text{m}^2 \text{g}^{-1}$. In this technique there are many advantages of using short columns instead of those currently used in high performance anion-exchange chromatography in terms of separation time.

On the other hand, cation resins in the lithium form have been used for similar analyses using 90% ethanol in water eluents. The use of 4 and 8% cross-linked cation-exchange resins in the calcium or silver form have been used to provide a rapid separation of oligosaccharides. It is possible to obtain a total analysis of material applied to the column and the use of water as the only eluent (Figure 4).

An early approach to reduce stationary phase mass transfer resistance was to form thin ion-exchange shells on the surface of an impervious core, e.g. glass beads to give 'pellicular' materials. The major application of pellicular anion exchangers is in the chromatography of carbohydrates at $>\text{pH } 12$, where most carbohydrates become anionic and can be separated on a column packed with a strong anion exchanger. Because carbohydrates undergo chemical changes on prolonged exposure to strong alkali, the separation time must be short.

Figure 3 Separation of starch-derived oligosaccharides on an *in situ*-modified silica column using 1,4-diaminobutane (0.01% v/v) as modifier. Numbers refer to the degree of polymerization of the oligosaccharide. Gel permeation chromatography There has been no direct replacement for the cross-linked polysaccharide or polyacrylamide materials used for traditional gel permeation analysis of oligosaccharides. Some advances have been made with the development of silica matrices deactivated by chemical bonding of an organic ether stationary phase to provide a hydrophilic surface.

Fractionation ranges extended down to 10–12 units whilst bare silica can extend the fractionation range down to 5–6 units. Even with the modified materials, adsorption effects are present and elution with ionic buffers is recommended within the pH range 2–7.

Water-compatible hydroxylated polyether-based matrices have been developed which overcome some of the disadvantages of silica-based materials and have fractionation ranges which are comparable to the cross-linked polysaccharide and polyacrylamide gels. In spite of their lower selectivity compared to silica-based matrices, such materials have a very high stability towards alkaline pH (up to pH 12). Separation times are of the order of one-third to one-tenth

that of traditional low-pressure gel permeation analysis, but they are inferior to those currently obtained by ion-exchange chromatography. Consequently, less emphasis is placed on high performance gel permeation chromatography for oligosaccharide fractionation.

Detection Systems

Detection of oligosaccharides eluting from HPLC columns is the biggest challenge and weakest link in the analysis of polysaccharides. When sensitivity in the submicrogram range is required the only method readily available is the use of pre-column derivatization with separation via adsorption chromatography and detection via UV monitoring or pulsed electrochemical detection at noble metal electrodes. Attempts to use strong cation-exchange resins to hydrolyse the glycosidic bonds in polysaccharides to give complete conversion to monosaccharides and lower oligosaccharides after chromatographic separation has been reported with the resulting saccharides being detected as reducing compounds.

Direct Detection

UV absorbance Carbohydrates do not absorb light in the UV or visible range and have no fluorescence. Polysaccharides, however, do absorb at wavelengths in the far UV. The higher absorbance is at about 188 nm but, due to noise in the detection signal below 190 nm, detection is normally performed at wavelengths between 192 and 200 nm. The response, depending largely on the freedom of the carbonyl

Figure 4 Separation of starch-derived oligosaccharides by high performance ion-exchange chromatography using 4% cross-linked cation-exchange resin with silver counterions (1, 2, 3, etc., refer to the degree of polymerization of the oligosaccharide; HMW, high-molecular-weight material above). (Reproduced with permission from Chaplin MF and Kennedy JF (eds) (1994) *Carbohydrate Analysis: A Practical Approach*, 2nd edn, p. 50. Copyright IRL Press Limited.)

group, differs between the polysaccharides. Analyses are restricted to solvents such as acetonitrile–water mixtures that do not absorb significantly at these wavelengths. Oligosaccharides containing acetamido groups or sialic acids can be detected by absorbance in the range 180–220 nm with a detection limit of approximately 1 nmol. The best signal-to-noise ratio for a range of carbohydrates is found between 195 and 210 nm.

For preparative separations, a higher wavelength can be used. The sensitivity decreases by 10- and 100-fold by increasing the wavelength of detection from 208 to 218 and 228 nm. Polysaccharides having unsaturated monosaccharides formed by enzymic digestion of sulfated glycosaminoglycans have an absorption maximum at 232 nm. The sensitivity of detection of these oligosaccharides at 232 nm is less than 1 nmol.

The sensitivity can be further improved (down to 1 pmol) by introducing a strongly UV-absorbing group such as benzoyl or phenylisocyanate into the molecules. Diode array detection is a technique widely used in combination with reversed-phase HPLC for the separation and quantitative determination of polysaccharides. The detection limit obtained by this method is about 5 pmol. In the determination of the degree of polymerization of agar-type polysaccharides, samples are prepared adding 1 g of starch to 10 mL of 0.2 mol L⁻¹ trifluoroacetic acid, heating at 100°C for one hour, then adding 90 mL of absolute ethanol and storing at -70°C to allow precipitated saccharides to settle. It is also necessary to remove all remaining traces of ethanol by evaporation under nitrogen since ethanol interferes with retention of the larger oligomers. Finally, the dried residue is redissolved and filtered in deionized water prior to injection.

The simplest and ideal methods of detection are those that do not require chemical derivatization of the sugars but in order to increase the sensitivity of detection, they may be derivatized to give light-absorbing or fluorescent compounds before or after LC separation. This approach may be very useful, especially if it allows the use of efficient chemically bonded or underivatized silica columns.

The sensitivity of carbohydrate detection can be greatly increased by introducing a radioactive label, either by reduction with sodium boro[³H]hydride or de-*N*-acetylation and re-*N*-acetylation with [¹⁴C]acetic anhydride. Oligosaccharides isolated from biological sources are often obtained in reduced and/or de-*N*-acetylated form. Analysis of reduced oligosaccharides has an additional advantage in that reduction destroys the anomeration at the reducing end, thus simplifying chromatography and subsequent structural analysis.

The separation of anomers is also given by HPLC after pre-column derivatization of reducing oligosaccharides with acetyl, benzoyl and phenylisocyanate groups. Therefore, reduction is usually performed routinely as part of these derivatization procedures. The sensitivity of detection of the latter two derivatives by UV would usually obviate the need to introduce a radioactive label.

Several online radioactive detection systems are available with both solid scintillant cells and the possibility of addition of liquid scintillant, for example, from Berthold, Beckman and Nuclear Enterprises. For ³H-labelled oligosaccharides, approximately 10⁴ and 10² cpm are required for detection by the two types of measuring technique. The sensitivity of detection of ¹⁴C is of order of 10³ cpm.

Early post-column derivatization methods for carbohydrate detection employed strong acids and thus required acid-resistant equipment. For example, the use of orcinol–concentrated sulfuric acid reagent required an elaborate carbohydrate analyser to be set up for direct post-column detection. Similar methods, such as the phenol–sulfuric acid assay, have proved useful for separate, off-column hexose determination. The sensitivity of detection for these methods is approximately 20 nmol hexose which is slightly less than by UV detection of native oligosaccharides containing hexose and hexosacetamido sugars, but represents a greatly improved sensitivity for detection of oligosaccharides containing neutral sugars alone.

More recent post-column derivatization methods have used noncorrosive reagents, particularly for detection of reducing sugars after borate-complex ion-exchange chromatography. The copper complexes of 2,2'-bicinchoninate, ethanolamine–boric acid and 2-cyanoacetamide, for example, have been used to detect 1 nmol oligosaccharide. Detection of less than 1 nmol oligosaccharide has been reported using tetrazolium blue reagent (3,3'-[3,3'-dimethoxy-1,1'-biphenyl-4,4'-diyl]bis[2,5-diphenyl-2H-tetrazolium] dichloride) which has the additional advantage of achieving this sensitivity in the absence of borate buffer and at a lower reaction temperature of 85°C. The method is suitable for both reduced and reducing oligosaccharides.

The ammoniacal cupric sulphate assay is sensitive but simple and avoids the corrosive reagents and complex heating/mixing protocols of some other post-column detection methods. It is of general application to substances that react with cuprammonium, for example, carbohydrate derivatives and glycols, and is not sensitive to changes in the solvent composition. Monosaccharides do not seriously interfere in this assay if the periodate oxidation reaction

takes place below 40°C and they are not present in an overwhelming excess. They can be detected if the periodate oxidation is allowed to take place at a higher temperature (e.g. 100°C). Periodate oxidation alone may be used for post-column detection of cyclitols, aldoses, alditols and ketoses by monitoring the absorbance at 260 nm. Assay with cyanoacetamide uses noncorrosive reagents, shows good linearity and is highly sensitive for aldoses, hexosamines and alduronic acids. The fluorescence is quenched by acetonitrile, if present in the eluate, but the absorbance is unaffected.

Refractive index and light-scattering detection A detection method of general applicability makes use of changes in refractivity. It is at least ten times less sensitive than UV detection due to high background noise caused by temperature fluctuations and pump pulsations.

Many of the early HPLC studies on carbohydrates used a differential refractive index detector because these studies were carried out on oligosaccharides containing neutral sugars only, which absorb weakly in the UV region. The disadvantages of using a refractometer are that only isocratic elution is possible and the sensitivity is relatively low, 10–100 nmol being required for detection.

Light scattering (LS) can be used for measuring the molar mass of polysaccharides. Several polysaccharides have been routinely characterized by LS for the determination of the molecular weight distribution. The molecular weight distribution can be used to determine the polydispersity (M_w/M_n) and the heterogeneity in a sample.

Electrochemical detection of polysaccharides Nanomolar detection of both reducing and reduced neutral oligosaccharides and polysaccharide hydrolysates has been reported using pulsed amperometric detection (PAD) employing a gold electrode. This method is stated to have the advantage of increased detector durability compared with potentiometric and single potential detectors. Detection of carbohydrates in the presence of a high concentration of potentially interfering salts is also possible. An increased sensitivity for detection of reducing sugars (down to 1 pmol) has been reported using amperometric detection of polysaccharides chromatographed in sodium phosphate buffer after post-column reaction with copper bis(phenanthroline) in alkaline solution at 96°C.

PAD, in conjunction with high-pH anion-exchange chromatography, has also become the method of choice for analysing sugars. Their direct electrochemistry on noble metal electrodes suffers from electrode

fouling due to absorption of oxidized species on the electrode surface. PAD overcomes this problem by using a triple-step potential waveform. In the first step (data recording), the gold electrode is held at a potential suitable for oxidation of the analyte. The second step raises the potential to some higher value, where absorbed oxidation products are oxidized further into mobile phase-soluble products, thereby cleaning the electrode. Finally, the electrode generates a new gold oxide surface. Using this technique, closely related saccharides can be separated and detected in the 10 to 100 pmol range.

Analysis of Complex Mixtures

HPLC of glycopeptides is not widely developed because of peptide interferences. In fact, a given glycan located in a given peptide sequence of the protein generally gives rise to a mixture of glycopeptides due to the random nature of proteolytic action. Chemical or enzymatic removal of glycans from such complex mixtures solves this problem and allows the use of HPLC. It is possible to use different HPLC techniques such as:

- anion-exchange chromatography of sialyloligosaccharides (Figure 5A);
- partition chromatography of neutral and acidic oligosaccharides on primary amine-bonded silica or alkyl diol-bonded silica (Figure 5B);
- reversed-phase chromatography of neutral oligosaccharides on C_2 and C_{18} -bonded silica (Figure 5C).

Conjugation of two fluorescent ortho-substituted aniline derivatives, 2-aminobenzamide (2-AB) and 2-anthranilic acid (2-AA), to *N*- and *O*-glycans have been recently investigated. Conjugation conditions for attaching 2-AB and 2-AA to core-fucosylated and nonfucosylated glycans have been developed using complex *N*-glycans radiolabelled at the nonreducing terminus with [3H]C₆-galactose.

Most glycolipid separations have involved derivatizing the glycolipids to allow UV detection. The derivatives are usually benzoyl or *p*-nitrobenzoyl esters and the columns are based on silica gel. For instance, ceramides (0.1–1.0 mg) are dissolved in 20% benzoyl chloride in 0.6 mL of dry pyridine and heated at 60°C for 1 h. The solvent is evaporated to dryness in a stream of N₂ and taken up in a small volume of hexane for injection into the liquid chromatograph. The mobile phase is a linear gradient system of 0.20% methanol to 0.75% methanol in hexane. The detector operates at 254 nm and the minimum detection is about 10 pmol of each glycolipid.

(C) HPLC on alkyl diol-bonded silica of oligomannoside-alditols from the urine of a patient with a mannosidosis. M₂G-ol to M₉G-ol: oligomannoside-alditols containing from 2 to 9 mannose residues. (Reproduced with permission from Chaplin MF and Kennedy JF (eds) (1994) *Carbohydrate Analysis: A Practical Approach*, 2nd edn, pp. 155, 157 and 158. Copyright IRL Press Limited.)

The *p*-nitrobenzoyl derivatives are more sensitive to UV detection than the benzoyl derivatives but the benzoyl derivatives are better separated than the

p-nitrobenzoyl derivatives. A problem exists for regenerating the native glycolipide. It is not too difficult to remove *O*-benzoyl groups but the *N*-benzoyl group on amino sugars and in the ceramide fragment are far more difficult to remove. The use of a catalyst such as 4-dimethylaminopyridine in the benzoylation reaction with benzoic anhydride produces only *O*-benzoyl substitution.

Determination of the Position of Glycosidic Linkages. Combined HPLC and Mass Spectrometry (HPLC-MS)

Oligosaccharides released from human transferrin have been derivatized with 2-aminoacridone (2-AMAC) prior to analysis by either reversed- or normal-phase HPLC. Collected fractions of 2-AMAC-derivatized glycans have been analysed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, before and after desialylation (Figure 6).

A procedure for analysis of a mixture of neutral and acidic sugars in bacterial whole-cell hydrolysates using high performance anion-exchange liquid chromatography-electrospray ionization-tandem mass spectrometry (HPAEC-ESI-MS-MS) has been described. HPAEC is well established as a high-resolution chromatographic technique, in conjunction with pulsed amperometric detection. Alternatively, for more selective detection, sugars (as $M-H^-$ ions) are monitored using ESI-MS. Sugar identification is achieved by MS-MS using ESI.

Another simple, sensitive method for the structural characterization of oligosaccharides by fast atom bombardment-mass spectrometry (FAB-MS) has been designed. Oligosaccharides are labelled with a UV chromophore (which also serves as a charge-stabilizing group) and with a hydrophobic alkyl tail. The chromophore, a 2,4-dinitrophenyl group, aids UV detection and stabilizes negative ion species formed during analysis by FAB-MS. The hydrophobic tail, provided by an octyl group, enhances the surface activity of the analytes and makes them amenable to separation on a C18-bonded phase. This method has been applied to the structural analysis of the components of a mixture of starch maltodextrins with a degree of polymerization 1-16, to the analysis of the structure of pure maltohexose, and to a previously characterized oligosaccharide from *Rhizobium* capsular polysaccharide.

HPLC technology has been developed that is capable of resolving subpicomolar quantities of mixtures of fluorescent-labelled neutral and acidic

Figure 6 Reversed-phase HPLC analysis of glycan mixture from transferrin: (A) untreated; (B and C) digested with sialidase and a mixture of sialidase and fucosidase, respectively, prior to derivatization with 2-aminoacridone. glycans simultaneously and in their correct molar proportions. The reproducibility of the separation system, the predictability of glucose unit values, and the quantitative response of the detection system for individual fluorescently labelled glycans allows automation for the analysis of neutral sugars using a combination of enzymes as in the reagent array analysis method (RAAM). In addition, the simultaneous

resolution of both acidic (sialylated) and neutral products from the RAAM digestion allowed direct analysis of sialylated glycans, eliminating the previous need to remove sialic acid residues in a preliminary step.

Future Developments

As shown above, the greatest advances in the detection and characterization of polysaccharides will evolve from advances in mass spectrometry. The current ability to identify, with little ambiguity, virtually any high-molecular-weight biopolymer via the electrospray interface between HPLC and MS will continue to improve, in terms of ease of use, lower sample requirements and higher molecular-weight ranges. Advances will use detection techniques incorporating the strengths of each technique in sequential detection schemes. UV detection prior to MS is already common. Improvements will also come about with regard to the mapping of carbohydrates and polysaccharides.

The emphasis for the future does not appear to reside in reaction detection for HPLC of polysaccharides, but rather in more sophisticated instrumental methods of detection. Electrochemistry seems to hold much appeal, and yet it has not realized its full potential. Pulsed amperometric detection methods are maturing; chemically modified electrodes can be much more selective and sensitive than glassy carbon or Au/Hg-type electrodes. Multiple-array detectors, perhaps with chemically modified electrodes or different noble metal electrodes (Ni, CuO), may also provide more information of a qualitative nature. Current detection methods such as UV-visible, fluorescence and light scattering will always be useful for qualitative information, identification of the chromatographic performance of a peak, and for absolute quantitation, but they may never provide 100% specific information about the structure. On the other hand, the use of circular dichroism or optical rotary dispersion for detection of the conformation of polysaccharides can be equally used.

POROUS GRAPHITIC CARBON: LIQUID CHROMATOGRAPHY

M.-C. Hennion, Laboratoire Environnement et Chimie Analytique, Paris, France

Copyright © 2000 Academic Press

Introduction

Various carbonaceous sorbents have been used successfully since the early days of gas chromatography (GC), but for many years their application to liquid chromatography (LC) was unsuccessful. Active carbons with high specific surface areas were shown to be microporous and to contain polar groups at their surface, which provided poor LC performance. Graphitized carbon blacks (GCBs) lacked sufficient mechanical strength to withstand high LC pressures, in addition to having polar surface groups. In the 1970s, bonded silicas were extensively developed, but they had some disadvantages including solubility in the eluents, hydrolysis of the bonded chain at low or high pH, and the effects of the unavoidable unreacted silanol groups. Several attempts were made to prepare graphite-based sorbents that would not suffer from the disadvantages of bonded silica sorbents, but it was not until 1979 that Knox and Gilbert patented a method for making a robust porous carbon that possessed the required properties for use in LC. An improved version of this material became commercially available in 1988 under the tradename Hypercarb®. Although one or two other carbons made by

Japanese workers are sometimes mentioned, most of the studies and applications described in the literature utilize the porous graphitized carbon (PGC) Hypercarb®.

The properties of PGC come from its highly ordered crystalline structure composed of large flat layers of carbon atoms. It has proven to be unique, behaving as a stronger reversed-phase sorbent than any other existing reversed-phase packing or as a normal-phase sorbent. Separations of both nonpolar and highly polar mixtures can be performed that are impossible with other sorbents. Resolution of anionic and cationic analytes can be achieved in one run. These properties are partly explained by a retention mechanism that is quite different from that of other LC stationary phases. The properties of PGC are discussed here together with some selected applications.

Structure and Characteristics of PGC

PGC is obtained by impregnating a porous silica with a phenol–formaldehyde mixture. This mixture is polymerized within the pores of the silica gel and carbonized at 1000°C. The silica is then removed by dissolution in a concentrated (5 mol L⁻¹) sodium hydroxide solution. Graphitization is performed in the temperature range 2000–2800°C to remove the micropores. The resulting macroporous material has a flat crystalline surface.

Figure 1 Structure of (A) 3D graphite and (B) 2D porous graphitic carbon.

PGC does not have the true graphite structure, in which layers are well organized in three dimensions, as shown in **Figure 1A**. Rather it has a two-dimensional (2D) graphite structure composed of layers of hexagonally arranged carbon atoms in the sp^2 hybridization. The close intertwining of the graphitic sheets provides the rigidity and mechanical stability. The layer spacing is slightly larger than in 3D graphite, as shown in **Figure 1B**.

PGC meets the required properties for a good LC sorbent. It is available in a narrow particle-size distribution with mean particle diameter of 5 or 7 μm , it has an average specific surface area of $120 \text{ m}^2 \text{ g}^{-1}$, a uniform pore structure with mean pore diameter of 25 nm, and a porosity of 75%. Designed to withstand pressures of more than 400 bar, PGC is geometrically stable and free from any swelling or shrinking. It is inert to the common organic eluents and to extremes of pH. In the early stage of commercialization, some columns packed with the 7 μm material lacked efficiency, but significant improvements have been made and the 5 μm packing now available has a guaranteed efficiency of $60\,000 \text{ plates m}^{-1}$ and offers batch-to-batch reproducibility.

The flat homogeneous surface of PGC is responsible for its unique selectivity to geometrical isomers. The extensive layers of carbon atoms containing delocalized π electrons and the high polarizability are responsible for its unique retention mechanism.

Retention Mechanism

Mobile-Phase Effects: Reversed-Phase Behaviour for Polar and Nonpolar Analytes

The reversed-phase behaviour of PGC towards nonpolar and polar analytes has been observed in many

applications. **Figure 2** shows plots of the logarithm of the retention factor of phenol, 1,3-dihydroxybenzene (resorcinol) and 1,3,5-trihydroxybenzene (phloroglucinol) against the methanol volume fraction (ϕ) in a water/methanol mobile phase for PGC and two other reversed phases, C_{18} silica and the styrene-divinylbenzene porous copolymer PRP-1. Two important features of PGC are highlighted in this figure. First, the addition of methanol to the mobile phase results in a similar decrease in retention for all three sorbents, thus showing a classical reversed-phase dependence. However the retention values, and in particular the retention order, indicate that the behaviour of PGC is different from that of the other two materials for the analytes considered in this figure.

Retention of Nonpolar Analytes: A Strong Hydrophobic Sorbent

Since PGC was produced with the objective of being an improved reversed-phase material compared with the widely used C_{18} silicas, the first applications were made with nonpolar analytes, and PGC is described as a stronger hydrophobic sorbent than C_{18} silica. A common way of comparing the hydrophobicity of sorbents is to measure the effect of the addition of a methylene group in an homologous series. The methylene increment is 4.5 and 3.8 for the n -alkanols on PGC and C_{18} silica, respectively, with pure water as mobile phase. Kriz and co-workers compared the retention of 52 aromatic hydrocarbons, mostly alkylbenzenes, on PGC, C_{18} silica, phenylsilica, silica and alumina. **Figure 3** shows the variation of the retention factor on PGC according to the number of carbon atoms for both the series of n -alkylbenzenes and the series of methylbenzenes. The methylene increment measured for the n -alkylbenzenes was 0.22 using PGC with pure methanol, compared with

Figure 2 Variation of the retention factors ($\log k$) with the mobile phase composition obtained on (A) LiChrosorb RP-18, (B) PRP-1 and (C) PGC. Solutes: \blacklozenge , phenol; \bullet , resorcinol; \blacktriangle , phloroglucinol. ϕ is the volume fraction of the mobile phase. (Reprinted from Coquart V and Hennion M-C (1992) Trace-level determination of polar phenolic compounds in aqueous samples by HPLC and on-line preconcentration on porous carbon. *Journal of Chromatography* 600: 195–201. Copyright (1992) with permission from Elsevier Science.)

values of 0.17 and 0.10 with C_{18} silica and phenyl-silica using a methanol/water mobile phase (80 : 20 v/v). Another important feature that can be seen from Figure 3 is the possibility given by PGC for discriminating between the two series. In the same study it was shown that C_{18} silica is unable to differentiate between the addition of a methylene group to an alkyl chain and the addition of methyl group to the benzene ring. A very slight difference could be observed on phenylsilica. Silica and alumina with pentane as mobile phase could discriminate between the two series, but with a methylene increment close to zero for the n -alkylbenzene series. This study illustrates well with the higher hydrophobicity of PGC over C_{18} silica as a reversed-phase sorbent for these nonpolar analytes, as well as its superior selectivity towards isomeric compounds.

Retention of Very Polar Analytes: Comparison with a Hydrophobic Reversed-Phase Mechanism

Several studies have shown that PGC does not behave as a perfect reversed-phase sorbent. Figure 2 shows that the same order is observed for C_{18} silica and

PRP-1 and that the retention factor decreases with the analyte's polarity from phenol to resorcinol and phloroglucinol. Plots of phloroglucinol for C_{18} silica have not been reported because this analyte is too polar to be retained with a methanol-rich mobile phase; it has been proposed as an experimental probe for the determination of the void volume of C_{18} columns. This corresponds to a retention mechanism based on hydrophobic interactions. The higher retention observed with PRP-1 is explained by additional π - π interactions between these aromatic analytes and the styrene-divinylbenzene matrix of the PRP-1 sorbent.

On PGC, the retention increases with the number of hydroxy groups. There is a great difference in retention for phloroglucinol with retention factors in water, k_w , of 1050 with PGC, 3 with PRP-1 and 0.3 with C_{18} silicas. Values of $\log k_w$ have been extrapolated from the variation of the retention factors in water/methanol mixtures from curves similar to those in Figure 1. These values, which allow comparison with C_{18} silicas and the apolar copolymer PRP-1, are reported in Table 1 for some mono-, di- and tri-substituted benzene derivatives.

Figure 3 Dependence of $\log k$ values for polymethylbenzenes and n -alkylbenzenes on carbon numbers. Packing material: graphite; eluent: methanol; temperature 20°C. Broken line drawn through points for the polymethylbenzenes; full line drawn through points for n -alkylbenzenes. (Reprinted from Kriz J, Adancova E, Knox JH and Hora J (1994) Characterization of adsorbents using aromatic hydrocarbons. Porous graphite and its comparison with silica gel, alumina, octadecylsilica and phenylsilica. *Journal of Chromatography A* 663: 151–161. Copyright (1994) with permission from Elsevier Science.)

First, when comparing values for monosubstituted benzenes, compounds are more retained by PRP-1 than they are by PGC or C_{18} silica. The comparison between C_{18} silica and PGC indicates that some solutes are less retained and some more retained by PGC than they are by C_{18} . The di- and tri-substituted benzenes listed in Table 1 are rather polar compounds and are either not, or only slightly, retained by C_{18} silicas, which explains why the $\log k_w$ values have not been reported. The comparison between the retentions on PRP-1 and on PGC are informative.

Table 1 Comparison of reversed-phase sorbents using extrapolated $\log k_w$ values obtained with C_{18} silica, PRP-1 and PGC

Solute	C_{18}	PRP-1	PGC
<i>Monosubstituted</i>			
Benzene	2.2	3.5	1.45
Aniline	1.08	2.5	1.35
Phenol	1.55	2.4	1.8
Benzoic acid	1.9	3.2	2.4
Nitrobenzene	2.05	3.6	2.45
<i>Di- and tri-substituted</i>			
4-Aminophenol		1.1	2.05
1,4-Diaminobenzene		1.2	2.4
4-Aminobenzoic acid		2	2.85
4-Hydroxybenzoic acid		2.3	2.7
3,5-Dihydroxybenzoic acid		1.35	3
1,3-Dihydroxybenzene		1.35	2.35
1,4-Dihydroxybenzene		0.83	2.15
1,3,5-Trihydroxybenzene		0.5	2.7

With PRP-1, the $\log k_w$ values obtained with two polar substituents are always lower than those measured for each corresponding monosubstituted benzene, whereas the opposite is observed with PGC. For example, $\log k_w$ of aminophenol is 1.1 with PRP-1 and is lower than both $\log k_w$ of phenol (2.4) and aniline (2.5). With PGC, $\log k_w$ of aminophenol is 2.05 and is higher than $\log k_w$ of both phenol (1.8) and aniline (1.35). Since on C_{18} silicas and PRP-1, the retention order is correlated with the polarity of the molecules, but not on PGC, the retention mechanisms must, therefore, be very different.

Many studies have been carried out on the retention mechanism on C_{18} silica, which has been shown to be primarily governed by hydrophobic interactions between the analytes and the carbonaceous moieties of the alkyl chain bonded at the silica surface. The octanol–water partition coefficient (K_{OW}) has been shown to be a good measure of the hydrophobicity of compounds. To a first approximation, the retention order is linked to this octanol–water partition coefficient as shown in Table 2, which lists the $\log k_w$ values obtained for the three reversed-phase materials and the $\log K_{OW}$ values for the very polar degradation products of triazines. The $\log k_w$ values decrease with $\log K_{OW}$ values for both C_{18} silicas and PRP-1 and analytes are no longer retained when compounds become very polar and more soluble in water than in octanol, as shown by negative $\log K_{OW}$ values. On PGC, the $\log k_w$ values also decrease with $\log K_{OW}$, but only slightly and they are still very high for the water-soluble analytes.

An extensive study has measured or estimated $\log k_w$ values for 46 polar benzene derivatives. The correlation between $\log K_{OW}$ and $\log k_w$ is shown in Figure 4. The relationship is good on C_{18} silica. With PRP-1, $\log k_w$ values are more scattered but the relationship is still acceptable. On PGC, there is no relationship at all except for n -alkylbenzenes, and a high retention is observed for very polar compounds with $\log K_{OW}$ values between 0 and 1.5.

The high retention of very polar analytes, particularly those in an ionized form, is a key property that has been explored for extraction purposes. The trace analysis of water-soluble pollutants requires an extraction step before analysis, the parameters of which can be predicted from LC data, especially $\log k_w$ values. PGC is the only sorbent able to extract from water very polar degradation products, such as those reported in Table 2.

The delocalization of the π electrons in the large graphitic bonds and the high polarizability of the carbon are responsible for strong induction interactions in addition to solvophobic interactions. The result is that the presence of hydrophilic groups in the

solute molecule does not cause as great a retention decrease on carbon as on C_{18} silica. Any molecular mass increase in the solute, be it in hydrophobic or dipolar moieties, tends to cause a retention increase.

The term ‘hydrophobic adsorption’ was introduced to characterize the positive interaction between the PGC and the solute, as opposed to the ‘hydrophobic partitioning’ observed with C_{18} silica. When polar

analytes are of interest, the electronic interactions have been shown to be more important than the hydrophobic interactions in the retention mechanism. The exploitation of data shown in Figure 4 has demonstrated that the relative position of the substituents on the ring is important and that retention on PGC is very sensitive to the electronic density of the solute molecule. The effect of the polarity of the solutes, taking into account field and resonance effects, has been studied using local dipolar moments and the overall electron excess charge density. The analyte retention factors of polar analytes can be predicted through correlation between $\log k_w$ and the electron excess charge density.

Selection of the Mobile Phase: Solvent Strength

Few attempts have been made to establish the eluotropic strengths (ϵ^0) of commonly used organic solvents with PGC. Using the Snyder equation, the results indicate that the range of solvent strengths for any eluent is small compared with that of silica base sorbents (about 0.2 unit compared with 1 unit). There is no PGC eluotropic series similar to that of silica or alumina. Another result is that the ϵ^0 value for any eluent may depend upon the solutes or the group of solutes used to determine it. However, the evidence confirms that water is undoubtedly the weakest solvent. Methanol and acetonitrile are shown to be of equivalent weakness, while dioxan, tetrahydrofuran (THF) and dichloromethane have the strongest elution strengths. The elution strength of hexane has been shown to depend strongly on the polarity of the analytes, but is generally intermediate between methanol or acetonitrile and THF.

The retention factors of some pesticides and other organic pollutants measured using a PGC column eluted with methanol, THF and methylene chloride are reported in Table 3. The results show that retention can be very high with methanol and that THF and methylene chloride are stronger eluents. Measurements performed with acetonitrile indicate that the retention factors are similar to those obtained with methanol. Once more, there is no apparent relationship between polarity and retention of compounds. A polar pesticide such as metatritron is highly retained in pure methanol, and to a less extent by THF and methylene chloride.

It is important to realize that methanol or acetonitrile are similar weak solvents and compounds that will not elute with methanol will not elute with acetonitrile. Unlike C_{18} silica, the PGC column should not be washed with acetonitrile, and a stronger solvent such as dioxan or THF is required. If the retention of polar, ionizable analytes is too low, then ion-pairing agents can be used in the same way as in

reversed-phase LC to increase the retention. When compounds are strongly retained, the PGC surface can be modified by adsorption of various molecules such as trifluoroacetic acid (TFA) in order to reduce the retention of polar analytes. When looking at some of the values in Table 3, the high retention of phenanthrene in pure THF indicates that nonpolar analytes can be totally retained. The addition of a surfactant such as Tween 80 has been shown to reduce the retention of hydrophobic molecules by 15–20%.

Selected Applications

Geometrical Isomers and Diastereoisomers

PGC allows unique selectivity for geometrical and diastereoisomers owing to its flat structure. A typical example is the separation of phenol and *o*-, *m*- and *p*-cresol which can be achieved in less than 10 min, whereas it is impossible to separate *m*- and *p*-cresol on C_{18} silica. Other examples include the isomers of xylene, some ionizable isomers such as anisidic, toluic, bromobenzoic and nitrobenzoic acids, and the isomers of the corresponding basic forms (anisidine, toluidine, etc.).

Another interesting application from the environmental field is the pre-separation of the less toxic

PCBs from the more toxic non-*ortho* PCBs using hexane/dichloromethane (70 : 30 v/v) as an extraction solvent. A 50 × 4.6 mm column has been specifically developed for the purpose.

Enantiomers

PGC is not a chiral phase but it can be used as a support to separate enantiomers by the addition of chiral discriminators in the mobile phase. The advantages over silica-based sorbents is that the surface of PGC is homogeneous, which allows rapid equilibration. The separation of the enantiomers of a benzodiazepine can be achieved by the addition of β -cyclodextrin to the mobile phase. Another chiral discriminator, carbobenzoxyglycyl-L-proline, was used for the separation of the optical isomers of hydrophilic amino alcohols strongly retained on silica-based materials. The enantiomers were eluted in 5 min on PGC. Another advantage is that the range of chiral compounds can be extended to the whole pH range.

Instead of adding the chiral modifier to the mobile phase, Knox and Wan have coated the PGC with a near-monolayer of an adsorbed enantiomeric modifier (*L*- or *D*-isomers of *N*-(2-naphthalenesulfonyl)phenylalanine), which then acts as an adsorbed stationary phase. Separations of the enantiomers of amino- and hydroxy acids were obtained in this way.

Basic and Acidic Compounds

Because of their inertness, PGC columns can be used over the entire pH range without deterioration of column efficiency and are therefore well suited to the separation of basic or acid compounds. Separation of basic compounds on C_{18} silicas is sometimes difficult and often poor peak shapes are observed, owing to strong secondary ionic interactions between residual silanol groups and the basic analytes. Figure 5 illustrates the difference that was observed for the separation of monochloroanilines and hydroxychloro- or methylchloroanilines. On C_{18} silica (Figure 5A), the more polar 2-hydroxy-5-chloroaniline is eluted first and separation of the monochloroanilines requires a mobile phase containing 33% acetonitrile. On PGC (Figure 5B), monochloroanilines are eluted before 2-hydroxy-5-chloroaniline and the initial mobile phase contains 68% methanol. Little tailing is observed on PGC as compared to C_{18} silica. This has also been observed for the separation of aromatic amines and pyridine.

The use of extreme pH is illustrated by the separation of aromatic amino acids with a mobile phase at pH 1, or the separation of benzodiazepines carried out at pH 10.6. Another example is the separation of

Figure 5 Separation of aniline derivatives (A) using a C_{18} column and (B) using a PGC column.

water-soluble sugars, which can be ionized at high pH and retained by PGC through the use of ion pairing.

Ionic Compounds

In most cases, ions can be retained on PGC without the help of ion-pairing agents. Remarkable separations of small ionizable compounds of biomedical interest have been published by Lim *et al.* The retention of anionic compounds is explained by electronic interactions occurring between the lone pair electrons of the anionic analyte and the delocalized π bonds of the PGC. Examples include the determination of oxalic acid in human urine; this analyte is totally ionized in water and its separation from the other organic compounds in urine cannot be achieved using a C_{18} silica column. The combination of a sample preparation step using a C_{18} pre-column, which retains hydrophobic interferences but not oxalic acid, and a separation step with a PGC column, allows

Figure 6 Separation of pertechnetate (TcO_4^-), dioxo(bis-ethylenediamino)technetium, $[\text{TcO}_2\text{en}_2]^+$, and dioxo(1,5,8,12-tetraazadodecane)technetium, $[\text{TcO}_2\text{ta}]^+$, on PGCs (A) with 2% (v/v) acetonitrile in 0.1% TFA as eluent; (B) with 2% acetonitrile in 1% TFA as eluent; flow rate, 1 mL min^{-1} ; detector, radiometric. (Reprinted from Gu G and Lim CK (1990) Separation of anionic and cationic compounds of biomedical interest by HPLC on porous graphitic carbon. *Journal of Chromatography* 515: 183–192. Copyright (1990) with permission from Elsevier Science.)

oxalic acid to be separated from other polar compounds using a mobile phase containing 0.08% TFA. Creatine and creatinine can also be determined in urine and in serum within 8 min using 3% (v/v) acetonitrile and 0.1% TFA.

Anionic and cationic compounds can be separated simultaneously with a mobile phase containing an electronic modifier such as TFA and an organic modifier (e.g. acetonitrile). PGC has been used to separate pertechnetate anions (TcO_4^-) from other mono-cationic amine complexes as shown in Figure 6A with a mobile phase containing 2% (v/v) acetonitrile in 0.1% TFA. TcO_4^- is retained exclusively by electronic interactions while the cationic complexes are retained by hydrophobic reversed-phase interaction. The separation can be controlled precisely according to the nature of the interactions. Increase in the concentration of TFA had a significant effect on the retention time of TcO_4^- , as shown in Figure 6B. The TFA acts as an 'electronic modifier'. Modifying the acetonitrile content affected the retention of the two cationic complexes, but not that of the anionic TcO_4^- .

Ion exchange chromatography can be achieved by modifying the surface of the PGC polyethyleneimine, which is rendered insoluble by flushing the column with a phosphate buffer. This column provides good separation of simple anions and it has been verified that retention is by a simple ion exchange mechanism.

Highly Polar and Water-Soluble Analytes

The use of PGC for the separation of very polar analytes is an important area that is far from being fully explored. Some pertinent examples include the analysis of highly water-soluble carbohydrates, drug metabolites and polar pesticides and their degrada-

tion or transformation products. Many of the separations that have been performed in this area are not possible with other reversed-phase materials.

Monosaccharides can be directly eluted with water from PGC and disaccharides with water containing either 15% methanol or 4% acetonitrile, each peak being split into anomers. A range of alditols containing up to five monosaccharides has been separated using an acetonitrile gradient with 0.05% TFA by Davies *et al.* These workers concluded from the order of retention that the retention mechanism involved interaction of the polar segments of the carbohydrate with the delocalized electrons of the PGC layers. Other examples have been presented for the separation of mono- and disaccharides, sugar acids and sugar amines using mobile phases at pH up to 13.

Figure 7 shows an example of the separation of highly polar pesticides using an acetonitrile/water gradient with an initial content of 10% acetonitrile.

Figure 7 Analytical separation of polar pesticides using $10 \text{ cm} \times 0.46 \text{ cm}$ i.d. Hypercarb column packed with $5 \mu\text{m}$ particles; mobile phase: 0.005 mol L^{-1} phosphate buffer at pH 7 and acetonitrile, gradient from 10% acetonitrile to 15% from 0 to 5 min and up to 40% and 40 min. UV detection at 220 nm.

Figure 8 (A) Separation of (1) ammeline, (2) cyanuric acid and (3) ammelide using a 25 cm \times 0.46 cm i.d. C_{18} column (Spherisorb ODS) eluted with a 10^{-3} mol L^{-1} perchloric acid solution. (B) Analysis of a water extract from 250 mL of drinking water not spiked and (C) spiked with $5 \mu g L^{-1}$ of cyanuric acid. (D) and (E) Analysis of the same samples as in (B) and (C) using a Hypercarb analytical column eluted with methanol/0.05 mol L^{-1} phosphate buffer at pH 7 (30 : 70 v/v). UV detection at 220 nm. Extract from water obtained using a commercial solid-phase extraction cartridge packed with PGC.

With a similar gradient applied to a C_{18} column, the retention order is different and oxamyl and deisopropylatrazine (DIA) are only slightly retained. An-

other example is the separation of the polar degradation products of atrazine. Ammeline, ammelide and cyanuric acid (see Table 2) can be separated with an

aqueous mobile phase but with retentions close to the void volume of the column, as shown in **Figure 8A**. Therefore, when these analytes are to be determined in real water at trace levels, the extraction and concentration step generates many interfering compounds that hinder the detection of early eluted analytes, as shown in **Figure 8B** where peaks marked with the stars may correspond to the three analytes. **Figure 8C** corresponds to the extract spiked with cyanuric acid, but no sound conclusion can be made. It was verified that the water did not contain cyanuric acid because, using a PGC column, cyanuric acid is eluted within 8 min with a mobile phase containing 30% methanol. With this column and eluent there is no problem with the separation between the analyte of interest and the interfering coextracted analytes, which are eluted in the peak close to the void volume of the column with such a mobile phase (**Figure 8D** and **E**).

Future Trends

Designed to be the 'perfect reversed-phase material', PGC has been shown to possess a unique chromatographic behaviour, different from other reversed-phase materials. It makes possible the separation of many solutes over a wide range of polarities and is well suited for the separation of positional isomers. Its inert structure allows a complete pH range of eluents to be used, permitting a greater exploitation of the functionality of analytes. The possibility for modification of its surface has opened new areas of applications.

Its unusual retentive behaviour for polar analytes has led to separations that cannot be achieved with other available stationary phases. More work is undoubtedly necessary to achieve a better understanding of the unique behaviour of PGC.

The Polymer–Metal Complex as a Gas Adsorbent

Solid adsorbents are promising materials for gas separation. A separation is achieved by selectively adsorbing one of the components of a gas mixture onto the surface of a solid adsorbent. To achieve an efficient separation, high selectivity towards the targeted gas against others is necessary. Some metal complexes are quite useful for this purpose. For example, gaseous molecules with non-bonding electrons or π -electrons such as carbon monoxide (CO), ethylene (C_2H_4), and nitrogen monoxide (NO) are co-ordinated reversibly on transition metals (Cu(I), Fe(II), Ag(I), and so on). Thus, solid adsorbents for these gases can be prepared conveniently by immobilizing the corresponding metal complexes on a polymeric resin. The polymer–metal complexes thus formed have good selectivity for the gaseous molecules. However, the polymer used as a support for the metal complex can significantly affect the adsorption properties. For instance, polymer–metal complexes acquire fairly high durability against undesirable molecules compared with the metal complexes without polymer support due to the polymer effect. Another important property of the polymer support is its *porosity*, which regulates the efficiency of the gas separation.

Importance of Porosity for the Efficient Gas Separation

Generally, porous structures are required for useful solid adsorbents. For example, metal complexes supported on a non-porous (gel-type) polymeric resin do not show rapid adsorption, although the metal complex itself binds smoothly to the target molecule. The same phenomenon is observed in conventional physical adsorption processes. The high adsorption capacity of active carbon is mainly attributed to the extremely large surface area of this material ($S \cong 1000 \text{ m}^2 \text{ g}^{-1}$). Similarly, a porous structure is also essential for polystyrene resins which are applied industrially for separation processes. The same ma-

terials formed as round solid beads without physical pores are useless as adsorbents. The significance of the porous structure is well understood by the following simple calculation. In the case of a spherical polystyrene resin *without* porous structure, only the outer surface contributes to the surface area. The specific surface area per unit weight ($\text{m}^2 \text{ g}^{-1}$) is expressed in the following equation as a function of the radius (r nm) of the resin:

$$S = 3 \times 10^3 / (d \cdot r) \quad [1]$$

where d is the density of the polystyrene resin (in this case, d is 1.04 g cm^{-3}). To provide $100 \text{ m}^2 \text{ g}^{-1}$ of S to the polystyrene resin, r would be as small as 29 nm which corresponds to the size of colloidal particles. A nano-sized polystyrene powder is practically useless as an adsorbent so that the technology to provide porous structure is of critical importance.

Preparation of Porous Polymer Complex Adsorbent

Crosslinked polystyrene resin (Pst) is normally used as a starting material of the porous polymer–metal complex. Ways for preparing porous polymer complexes from this resin are illustrated schematically in Figure 1. Primarily, polystyrene resin itself needs to have a porous structure as a matrix. Porous polystyrene resin can be synthesized through special polymerization techniques which are demonstrated below (step 1 in Figure 1). Certain metal ions can form complexes with aromatic hydrocarbons so that the obtained resin is also available as a support without further chemical modification. Complexation of metal ions with polystyrene resin provides the porous polymer–complex adsorbent.

Various organic ligands for the complexation with target metal ions can be also chemically introduced into the porous polystyrene resin (step 2). In this method the porous polymer–complex is obtained by simple complexation of the chelate resin with metal ions. However, porosity can then be further enhanced through complexation of multivalent metal ions and treatment with an organic solvent (step 3). In the following sections, steps 1 and 3 in Figure 1, which are very important processes to prepare porous polymer complex adsorbents, are described in detail.

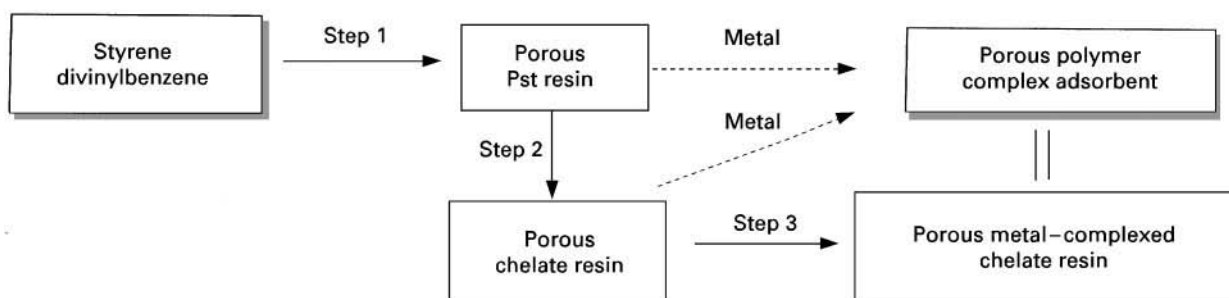

Figure 1 Processes for the preparation of porous polymer metal complexes.

Preparation of Porous Polymeric Resin

As mentioned in the previous section, the polymeric resin itself needs to have a porous structure to prepare porous polymer-metal complexes. Typically, high porosity is provided by the polymerization in the presence of a *porogen*. Generally, there are two methods for the preparation of porous polymers.

Addition of a precipitating solvent as a porogen

This method is based on polymerization in the presence of a *precipitating solvent* (porogen) which solubilizes styrene but not polystyrene. Typical precipitating solvents include heptane, *tert*-amyl alcohol (2-methyl-2-butanol), 2-butanol, and isooctane (2,2,4-trimethylpentane). When polymerization is carried out in the presence of these solvents, nano-sized microgels (polystyrene gel) are separated during the polymerization from the system as illustrated schematically in **Figure 2(A)**. These microgels are connected with each other during the copolymerization and form the three-dimensional network of the polymer beads. The resin obtained is an opaque white colour due to the physical pores formed in the beads.

In contrast, polystyrene resin prepared in the absence of the precipitating solvent is transparent. The nature of the beads (pore size distribution, specific surface area, and so on) can be regulated by the kind of porogen used, and various proportions of divinylbenzene and styrene.

Addition of a soluble linear polymer In this case, a molecular imprinting technique is applied for the pore generation. A soluble linear polymer (polystyrene) added as a template in the copolymerization system is incorporated into the resin. This linear polymer is finally eluted by the subsequent treatment of the resin with an appropriate solvent leaving a hole as illustrated in **Figure 2(B)**. Instead of a linear polymer, a reverse micelle composed of a surfactant (such as sodium bis(2-ethylhexyl)sulfosuccinate) can also be used as a porogen. Pore size distribution, surface area and total pore volume can be elegantly controlled by the size of reverse micelle formed in the copolymerization system.

Formation of metal complex with porous polystyrene resin These porous polystyrene resins themselves

Figure 2 Schematic illustration of the procedures for the preparation of porous crosslinked polystyrene resin. (A) Addition of a precipitating solvent as a porogen. (B) Addition of a soluble linear polymer.

(without chemical modification) are excellent supports of the metal complexes when benzene moieties function as ligands. Double salts such as AlCuCl_4 and AgAlCl_4 are easily immobilized on the polystyrene beads because they preferentially form complexes with π -ligands such as benzene and toluene. For instance, a porous polymer-metal complex of AlCuCl_4 can be prepared by the treatment of AlCuCl_4 and porous polystyrene resin in dry carbon disulfide followed by the evaporation of the solvent. Although a toluene solution of AlCuCl_4 is very unstable to water, the polymer-metal complex has high water-resistivity due to the protection of the polystyrene matrices. This polystyrene resin-immobilized AlCuCl_4 complex functions as an excellent adsorbent of CO (*vide infra*).

Complexation of Porous Polymer to Improve Porosity

The second technique (step 3 in Figure 1) to provide high porosity is based first on complexation with metal ions and secondly subsequent treatment with an organic solvent. The porosity of the styrene-divinylbenzene copolymer having iminodiacetic acid (IDA) moieties (chelate resin; CR, see Figure 5A) can be regulated by complex formation with metal ions, followed by treatment with organic solvents. Maximum porosity is achieved by complex formation of Fe(III) with chelate resin in water and subsequent washing with methanol ($S = 329.2 \text{ m}^2 \text{ g}^{-1}$), whereas no measurable pores are observed without this technique (specific surface area of the original sodium type of the resin is below $0.1 \text{ m}^2 \text{ g}^{-1}$). In the following sections, this technique is described in detail.

Treatment with an organic solvent The network of the polymer is not too rigid, but rather flexible when a small amount of crosslinking agent (divinylbenzene for polystyrene resin) is used. Therefore, the porosity of the resin can be altered by solvent treatment before desiccation. Generally, the porosity decreases when the resin swollen with a good solvent (a solvent which has high affinity with the resin) is desiccated whereas it increases by desiccation after treating the swollen resin with a less-swelling solvent. In the case of polystyrene resin, the porosity decreases by the desiccation from toluene; a good swelling solvent. High porosity is obtained when the resin swollen with toluene is desiccated after having been washed with methanol or acetone in which polystyrene resin cannot swell. The same is true for chelate resin-immobilized metal complex (CR-Me). The chelate resin swells in water due to the hydrophilic IDA moieties so that chelate resin dried from water does not exhibit high porosity. A porous polymer-metal complex can

be obtained by desiccation after having been washed with organic solvent such as methanol in which CR-Me cannot swell. For example, the specific surface area of CR-Fe(II) complex dried after treatment with methanol is $43.1 \text{ m}^2 \text{ g}^{-1}$ whereas that dried from water is as low as $3.2 \text{ m}^2 \text{ g}^{-1}$.

The increase in surface area on washing with an organic solvent is attributed to the suppression of shrinkage caused by the desiccation as illustrated in Figure 3. The CR-Me complex swollen in water keeps a rubberlike state (state A in Figure 3). When the solvent (water) in the resin is exchanged with an organic solvent miscible with water, many microgels are generated by a similar phenomenon to the 're-precipitation' of the polymer (state B). During exchange of the solvent, the resin complex is transformed from the rubberlike state into a glassy state because of the poor swelling in the organic solvent. In this glassy state, the shrinkage of the resin complex by desiccation is suppressed due to the low mobility of the polymer (state C). Consequently, surface area increases because pores produced in the resin complex remain. On the contrary, the resin complex swollen in water shrinks during the evaporation of water because the polymer chains have a high mobility in the rubberlike state (state D).

Efficient exchange of water in the resin with an organic solvent promotes the generation of microgels. Therefore, a solvent of high miscibility with water provides high porosity. The specific surface area of the CR-Fe(II) complex increases monotonously with increase in the solubility parameter δ as shown in Figure 4. Solvents with close δ values are very miscible with each other so that a large δ provides large porosity (note that δ of water is 47.9). Maximum porosity ($= 43.1 \text{ m}^2 \text{ g}^{-1}$ for CR-Fe(II) complex) is obtained from methanol which has the closest δ value ($= 29.7$) to that of water.

Complexation with metal ions of high valency The porosity of the CR-Me complex is also affected by the metal ions bound on IDA moieties as shown in Table 1. Metal ions with high valency are quite effective for providing a large surface area. The CR-Fe(III) complex prepared by desiccation from methanol has a maximum porosity ($S = 329.2 \text{ m}^2 \text{ g}^{-1}$), which is about 10 000 times larger than that of the original CR-Na(I) resin dried from water.

Metal ions (divalent and trivalent cations) are immobilized on CR through complex formation with IDA moieties, producing a 1 : 1 complex as shown in Figure 5(A). In addition to the solvent treatment, the electrostatic repulsion among the metal ions on IDA moieties also contributes to the suppression of the

Figure 3 Effect of solvent treatment of the swollen resin on the porosity.

shrinkage, which provides much higher porosity. Since interaction on a molecular level creates these pores, the size of pores generated by this method is smaller than 2.5 nm.

This phenomenon is characteristic of a chelate resin with IDA moieties. The reverse tendency is observed on crosslinked polystyrene sulfonate or polyacrylate. The porosities of these resins is decreased by high valent metal ions because anionic residues are cross-linked by the metal ions through electrostatic interaction as illustrated in Figure 5(B), which promotes shrinkage of the resin.

Gas Separation by Porous Polymer-Metal Complexes

Porous polymer-metal complexes prepared as above are available for efficient gas separation. High porosity directly contributes to the rapid adsorption of target gaseous molecules. In addition, the polymer matrix provides the adsorbent with durability against

contamination compared with the corresponding monomeric system. In the following subsections, separations of CO, ethylene, and NO are demonstrated in detail.

Adsorption of CO and C₂H₄ by Porous Polystyrene-Immobilized Metal Complex

A toluene solution of AlCuCl₄ reversibly absorbs gaseous CO molecules through co-ordination on Cu(I). Thus, immobilization of AlCuCl₄ on polystyrene resin provides an excellent solid adsorbent of CO. The adsorbent composed of porous crosslinked polystyrene beads (Bio-Beads SM-2, surface area 300 m² g⁻¹) and AlCuCl₄ rapidly adsorbs an equimolar amount of CO to the charged Cu(I) within 10 min at 20°C as shown by the solid circles in Figure 6. In contrast, it takes more than a day to reach equilibrium when a gel-type resin (Bio-Beads S-X1) is used as a support (open circles).

Since AlCuCl₄ complex reversibly coordinates C₂H₄, the same polystyrene-immobilized AlCuCl₄

Figure 4 Relationship between the specific surface area and the solubility parameter (δ) of the solvent used for washing the water-swollen CR-Fe(II) complex. The parameter δ corresponds to the square root of the cohesive energy density $(E/V)^{1/2}$, where E and V are the cohesive energy (energy of vaporization) and volume of unit weight of the solvent, respectively. If the δ solubility parameters of the two solvents are close to each other, it indicates that they have high mutual miscibility. Note that the δ value of water is 47.9. (Reproduced with permission from Toshima N, Asanuma H and Hirai H, *Bulletin of the Chemical Society of Japan* 62: 893–902 (1989), p. 901 by courtesy of the Chemical Society of Japan.)

complex also functions as a solid adsorbent of C_2H_4 . The same porous solid adsorbent binds 1.40 times as much C_2H_4 as the charged Cu(I) under the identical conditions of CO adsorption described above. Since a double salt of $AgAlCl_4$ binds C_2H_4 reversibly, porous polystyrene-immobilized $AgAlCl_4$ prepared in a same manner as $AlCuCl_4$ system also functions as a solid adsorbent of C_2H_4 . In this case, selective adsorption towards C_2H_4 against CO is achieved because it does not show binding activity to CO. Both $AlCuCl_4$ and $AgAlCl_4$ are so water-sensitive that toluene solutions of these double salts lose 70% of gas-binding activity by contact with 9000 ppm of water vapour for 10 min. In contrast, polystyrene-immobilized double salts maintain their initial gas-binding activities after contact with water vapour, due to the protection of the metal complex by the hydrophobic polystyrene.

Adsorption of NO by Porous Chelate Resin-Immobilized Fe(II) Complex

CR-Fe(II) complex The complex of Fe(II) and a polyamine *N*-carboxylate [ethylenediaminetetraacetate acid (EDTA), nitrilotriacetate acid (NTA), and IDA]

can bind NO through complex formation. Their aqueous solutions themselves are promising candidates for the absorption of NO because of their high capacity. A solid adsorbent of NO can be prepared by immobilization of above ligand on a polymer chain. For this purpose, the chelate resin involving IDA moieties is available. The porous polymer beads of the chelate resin-Fe(II) complexes which have been demonstrated in the previous section are quite useful as an adsorbent for NO.

Porous chelate resin-immobilized Fe(II) (CR-Fe(II)) complexes are prepared by desiccation of the complex after washing with methanol ($S = 43.1 \text{ m}^2 \text{ g}^{-1}$). The CR-Fe(II) complex shows such high NO adsorption capacity that almost all the NO is removed from 6 dm^3 of nitrogen containing 1000 ppm of NO within 25 min, as shown by the solid circles in Figure 7. On the other hand, the CR-Fe(II) complex prepared by washing with water ($S = 3.2 \text{ m}^2 \text{ g}^{-1}$) does not exhibit such a high adsorbing capability (open circles). The adsorption rate of NO linearly increases with an increase in the specific surface area of CR-Fe(II) complex. This fact clearly demonstrates that the improvement of the porosity contributes directly to rapid adsorption of NO. The adsorbent is completely regenerated by desorption treatment such as keeping the CR-Fe(II)-NO at 90°C under 3 mmHg for 3 h. The CR-Fe(II) complex can be repeatedly used for NO adsorption without significant deterioration.

Nitrogen monoxide is co-ordinated on the Fe(II) ion through 1 : 1 complex formation so that the following Langmuir adsorption isotherm can be applied for the detailed analysis of adsorption properties:

$$1/K = (P/[\text{CR-Fe(II)-NO}])[\text{CR-Fe(II)}] - P \quad [3]$$

where P is the partial pressure of NO (atm) and $[\text{CR-Fe(II)-NO}]$ is the amount of the NO adsorbed at equilibrium (mmol). From the linear plots of P against $P/[\text{CR-Fe(II)-NO}]$, the effective Fe(II) and the dissociation constant ($1/K$; atm) can be calculated from the slope and the intercept of the ordinate, respectively. Table 2 shows the results of Langmuir analyses of CR-Fe(II) complexes with different washing solvents (i.e. different surface area). The K values of each CR-Fe(II) complex is around $8 \times 10^3 \text{ atm}^{-1}$, which does not depend on the washing solvents. The equilibrium constant (K) is even larger than that of an aqueous solution of the Fe(II)-EDTA complex ($5.6 \times 10^3 \text{ atm}^{-1}$). By contrast, the amount of effective Fe(II) ion increases proportionally with the speci-

fic surface area caused by washing with an organic solvent. Thus, wash-treatment does not raise the complex formation constant K , but raises the amount of effective Fe(II) ions through an increase in the surface area.

Immobilization of Fe(II) complex on the polymeric resin has another advantage compared with the aqueous Fe(II) complex. As mentioned at the beginning of

this section, the complexes of Fe(II) and polyamine N-carboxylates (for example, IDA) themselves are promising candidates for the absorption of NO. But an aqueous solution of Fe(II)-IDA, a monomeric model of the CR-Fe(II) complex, readily deteriorates with oxygen through oxidation of Fe(II) to Fe(III) which does not absorb NO. In contrast, the CR-Fe(II) complex has some durability in the presence of oxygen. Both CR-Fe(II) complex and Fe(II)-IDA (each has 16.2 mmol of Fe(II)) can remove more than 90% of NO from 6 dm³ of nitrogen containing 1000 ppm of NO at room temperature before contact with air. In the case of Fe(II)-IDA complex, however, the amount of adsorbed NO decreases below 20% after contact of the complex with air for 60 min. About 80% of Fe(II) ions are oxidized by this treatment. In contrast, a decrease in the amount of adsorbed NO with the CR-Fe(II) complex is scarcely observed, and more than 50% of initially immobilized Fe(II) ions remain without oxidation. This distinct durability of CR-Fe(II) complex to oxygen is mainly attributed to the absence of water. The oxidation of Fe(II) is accelerated by the presence of water according to the following equation:

In the case of Fe(II)-IDA complex, water is inevitably required as a solvent so that oxidation of Fe(II) ions

proceeds rapidly. The polymer-metal complexes do not need solvents since metal complexes are dispersed on polymeric matrices. This is one of the advantages of polymer-metal complexes. Furthermore, oxida-

Ethanol	0.197	31.1	8.33
Acetone	0.144	17.1	6.67

*Binding constant CR-Fe(II)-NO complex formation as determined from Langmuir plots based on eq. [3]. (Reproduced with permission from Toshima N and Asanuma H, *Journal of Polymer Science, Part A Polymer Chemistry* 28: 907-922 (1990), p. 918 by courtesy of John Wiley.)

tion of Fe(II) ions in CR-Fe(II) is suppressed even in the presence of water, probably due to the protection of the metal complex by the polymer matrix.

Highly porous CR complex with mixed valences of Fe(II) and Fe(III) The CR-Fe(II) complex efficiently adsorbs NO, however, the ratio of the effective amount of Fe(II) ions with respect to total immobilized ions is only 0.14, indicating that the CR-Fe(II) complex does not fully exhibit its potential adsorbing capacity. To obtain the potential ability of CR-Fe(II), further enhancement of porosity is effective. Thus, Fe(III) is incorporated into the CR-Fe(II) complex in order to make the complex more porous. The chelate resin-mixed valence iron complex can be prepared by immobilizing both Fe(II) and Fe(III) ions simultaneously. Immobilization of a large amount of Fe(III) ions is preferable for high porosity. The mixed valence complex composed of 1.27 mmol of Fe(III) and 0.44 mmol of Fe(II) (per 1 g of the chelate resin involving 2.6 mmol of IDA moieties) adsorbs NO much more rapidly as expected. Specific surface area of the mixed valence complex is as large as 128.0 m² g⁻¹. Without Fe(III) ions (with 0.62 mmol of Fe(II) ions per 1 g of CR), rapid adsorption is not achieved due to the small porosity ($S = 5.3$ m² g⁻¹). Langmuir analysis (see Table 3) clearly demonstrates the role of each iron ion. Since the binding constant K of NO adsorption by the mixed valence complex is almost the same as that of the CR-Fe(II) complex, the active centre for NO adsorption of the mixed valence complex is identical with that of CR-Fe(II). The amounts of the effective Fe(II) ions for the mixed valence complex and CR-Fe(II) (determined from Langmuir plot) are 0.12 and 0.28 mmol, respectively as listed in Table 3. The value of the efficiency, R , of Fe(II) ions can be estimated from the ratio of the amount of effective Fe(II) to the amount of immobilized Fe(II). The efficiency R of the mixed valence iron complex is larger than that of the CR-Fe(II) complex due to an

Table 3 Amount of effective Fe(II) ions on CR-Fe(II) and mixed valence complex

Complex	Immobilized ion		Surface area (m ² g ⁻¹)	K* (10 ³ atm ⁻¹)	Effective Fe(II) (mmol g ⁻¹)	R [†]
	Fe(III) (mmol g ⁻¹)	Fe(II) (mmol g ⁻¹)				
CR-Fe(II)	0	2.01	43.1	8.33	0.28	0.14
CR-Fe(II), Fe(III)	1.27	0.44	128.1	10.0	0.12	0.26

*Binding constant of CR-Fe(II)-NO complex formation as determined from Langmuir plots based on eqn [3].

†Efficiency of Fe(II) immobilized on chelate resin determined as the ratio of effective Fe(II) to the amount of immobilized Fe(II). (Toshima N and Asanuma H, *Journal of the Chemical Society, Chemical Communications* 1989: 1075-1076, p. 1076 by the courtesy of Royal Society of Chemistry.)

increase in the surface area, demonstrating that the Fe(III) ions work by making the resin porous. The use of these two metal ions enables efficient NO adsorption.

The polymeric resin as well as the metal complex itself greatly affects the adsorbing ability for the target gas molecules as described in the case of CO, C₂H₄, and NO adsorption. It has been demonstrated clearly that large surface area directly contributes to the rapid adsorption of gaseous molecules. In some cases, the nature of the support dominates the whole adsorption property of the polymer-metal complex rather than the nature of the metal complex. Therefore, further regulation of porosity (e.g. pore size distribution) is quite significant in order to achieve efficient separation of the target gas. Metal complexes are promising compounds for reversible coord-

ination of gaseous molecules so that metal complexes immobilized on polymeric supports with properly regulated porosity will provide further useful materials for efficient gas separation.

Introduction

Polymers have been used as stationary phases in liquid chromatography (LC) for nearly 40 years. Initially they were used for size exclusion chromatography (SEC), a noninteractive means of separating molecules based on their size. This technique was originally applied to water-soluble macromolecules and is often referred to as gel filtration chromatography (GFC). Gel filtration describes the process particularly well: the stationary phase originally described

was a lightly cross-linked agarose in bead form, although other polysaccharides and also acrylamide-based materials are still employed today.

Characteristically such microporous gels are extremely soft and can easily be crushed. They do not possess a fixed pore structure and analytes can diffuse in and out of the aqueous swollen polymer particles. As a consequence column pressures must be minimized; reduced liquid flow rates and wide-bore columns are a necessity, resulting in extremely long run times. By 1964 a new polymeric stationary phase had been introduced based on cross-linked polystyrene. This material had sufficient cross-linker (in this case divinylbenzene) to ensure a high degree of physical strength when compared with earlier microporous

Figure 1 Representation of (A) solvated and (B) nonsolvated microporous beads and (C) a macroporous bead.

particles. The new polymer particles were also made in such a way that the network of pores within the beads was permanent and unaffected by the solvent used. Such particles, which are described as macroporous (**Figure 1**), immediately became useful for the size exclusion separation of organic-soluble macromolecules (or gel permeation chromatography, GPC, as it is commonly known).

Today many types of polymer are employed as stationary phases in chromatography, in both macroporous and microporous forms (**Table 1**). Their use is not restricted to SEC but also covers many aspects of adsorption-based chromatography.

Manufacture of Polymeric Particles

Most polymer-based stationary phases are manufactured as spherical particles, commonly using a suspension polymerization technique. Polystyrene, cross-linked with divinylbenzene (**Figure 2**), is perhaps the commonest form of synthetic polymer used in chromatography at the present time.

The manufacture of poly(styrene-*co*-divinylbenzene) particles, or PS/DVB, involves dispersing a mixture of the monomers including cross-linker and a suitable initiator, all dissolved in an appropriate solvent, into a larger volume of immiscible liquid, known as the continuous phase. Rapid stirring is used to produce the appropriate droplet size, at which point polymerization is triggered; in the case of an organic peroxide or persulfate this is achieved by heating, causing thermal decomposition of the initiator.

Table 1 Comparison between microporous and macroporous particles

<i>Microporous</i>	<i>Macroporous</i>
Low cross-link (< 12%)	High cross-link (> 20%)
High swell	Low swell
Variable pore size	Fixed pore size
Poor physical stability	Good physical stability
Low flow/low pressure applications	High flow/high pressure applications
Wide column diameters	Narrow column diameters

Figure 2 Chemical structure of poly(styrene-*co*-divinylbenzene).

Restricting the amount of cross-linker to less than 12% (by weight) produces a soft microporous particle, whereas using much higher levels of cross-linker (> 20%) produces a rigid particle. In order to introduce the pore structure, the solvent used to dissolve monomers and cross-linker must be a porogen. A porogen acts as a good solvent for the monomers but a poor solvent for the resulting polymer. Once polymerization commences, the growing polymer chain starts to precipitate into small globules, causing phase separation. The globules partially coalesce until all the monomers have been consumed, resulting in polymeric particles containing porogen-filled pores (**Figure 3**).

The particles are then thoroughly washed to remove all traces of porogen and any surface active agents that may also have been used during the manufacturing process. The resultant macroporous particles do not generally have the correct particle size distribution, particularly for high performance applications, and require further refinement by sieving or classification.

Figure 3 Representation of microspheres formed during suspension polymerization of a macroporous particle.

Size Exclusion Chromatography

The principle of SEC relies on the fact that smaller analytes can penetrate further into the bead, whether they are microporous or macroporous. This increases their residence time so that they elute later from the column. Large macromolecules may be excluded from the pore structure completely, whereas small molecules will totally permeate the accessible pore structure of the beads.

In the manufacture of macroporous particles the choice of porogen and the quantity used enables careful control of the resulting pore size and pore volume. It is thus possible to produce an extensive variety of different products for the analysis of various compounds covering a wide range of molecular weight distributions. Often it is not possible to find an individual column suitable for the analysis of a particular polymer and several different columns employed in series may be required. The actual selection process relies on the accurate calibration of individual columns with highly characterized polymer standards with narrow polydispersity (Figure 4).

The development of such techniques has progressed as equipment has been improved and packing materials have evolved. Modern highly efficient stationary phases tend to have a small particle diameter and are packed into relatively narrow bore columns (6–8 mm i.d.) in lengths of 20–60 cm. This has allowed SEC separations to be performed in minutes rather than hours.

Another recent development has been the use of mixed bed columns (Figure 5). It was discovered by Yau *et al.* in 1978 that by combining two or more packing materials with different individual pore sizes into the same column it was possible to extend the separation range of such a column, thus greatly simplifying the selection process.

Figure 4 Calibration curves for individual pore sized GPC columns. Column: PLgel, 300 × 7.5 mm, pore size as indicated; eluent: tetrahydrofuran; flow rate: 1.0 mL min⁻¹; detector: refractive index (RI).

Figure 5 Calibration curves for mixed-bed GPC columns. Conditions as for Figure 4.

While macroporous PS/DVB particles are ideally suited to GPC with organic solvents, such materials are extremely hydrophobic and are not satisfactory for use in SEC separations in an aqueous medium. To eliminate unwanted secondary interactions between the analyte and the stationary phase it becomes necessary either to coat PS/DVB particles with a hydrophilic layer or to move to a completely different polymer system that is inherently aqueous-compatible. Materials produced by both techniques are commercially available, as well as those from silica-based matrices. A polyhydroxyl coating, when applied to PS/DVB particles, can be immobilized by cross-linking it into place utilizing any remaining vinyl groups on the internal and external surfaces of the beads arising from unreacted divinylbenzene. A common alternative polymer system based on methacrylate monomers is also used to produce a range of hydrophilic macroporous particles suitable for GFC.

Reversed-Phase Chromatography

The macroporous polystyrene-based supports used for GPC have also been adapted to reversed-phase chromatography (RPC) applications. The PS/DVB matrix is sufficiently hydrophobic and, coupled with an extremely high internal surface area, this means that analytes partition between the mobile phase and the support in a similar manner to alkyl-bonded silica stationary phases (Figure 6).

Some small molecules may still be able to permeate the polymer structure itself despite the extensive cross-linking and so a stronger organic phase may be required. For example, using methanol as an organic phase can lead to excessive retention times unless it is used in the presence of a small amount of a stronger organic eluent such as tetrahydrofuran. Conversely acetonitrile rarely, if ever, presents any problems.

Figure 6 Reversed-phase separation of polyethylene glycol. Column: PLRP-S 10 nm 5 μm , 150 \times 4.6 mm; eluent: 40% acetonitrile; flow rate: 0.5 mL min⁻¹; detector: PL-EMD 960 evaporative light-scattering detector.

Given the aromatic electron-rich ring structure of the PS/DVB matrix, it is perhaps unsurprising that π - π interactions are sometimes observed, leading to longer than expected retention times for some compounds. This is in contrast with the acidic nature of silica-based material. Even high density coverage and extensive end-capping cannot completely eliminate residual silanol groups. These are frequently the source of band broadening of basic analytes, usually observed as a severe tailing of the peak.

The absence of any surface functionality or the need to modify the surface of PS/DVB with alkyl ligands results in an extremely inert stationary phase. This property can be exploited, allowing separations to be performed at pH 9 or above where even the most technologically advanced base-deactivated silica matrices will begin to degrade rapidly. In addition it allows sodium hydroxide solution to be used for clean-up and depyrogenation purposes, which is a significant benefit in preparative purification of pharmaceutical products. The properties of silica-based and polymeric reversed-phase materials are compared in Table 2.

PS/DVB stationary phases prove amenable to all aspects of conventional RPC including ion pair and ion suppression techniques. Figure 7 shows the separation of six proteins by reversed-phase ion pair chromatography.

For other forms of RPC, such as hydrophobic interaction chromatography (HIC), PS/DVB particles are too hydrophobic. The technique is principally applied to protein separations and relies on gradient elution profiles that run from high salt concentrations to low salt concentrations. At high salt concentration proteins are forced to interact with hydrophobic sites on the resin and are retained. As the salt concentration is

Table 2 Comparison between silica-based and polymeric reversed-phase materials

Alkyl-bonded silica	PS/DVB

Packed bed density $\sim 0.6 \text{ g mL}^{-1}$	Packed bed density $\sim 0.3 \text{ g mL}^{-1}$

decreased the proteins elute from the column. Polymeric materials suited to this type of application are hydrophilic matrices that have been modified to make them weakly hydrophobic by inclusion of a relatively low level of short chain alkyl groups or phenyl rings.

Ion Exchange

Ion exchange materials are frequently derived from polymers owing to the relative ease with which the appropriate ionic functionality can be introduced. Both strong and weak anion and cation exchangers can be formed on polystyrene supports and find use in a wide variety of application areas (Table 3).

One difficulty that can occur is due to nonspecific interactions arising from the hydrophobic nature of the PS/DVB backbone. This ‘feature’ has been exploited in related applications such as ion chromatography and ion exclusion chromatography, but for protein separations this property is less desirable. One solution is to coat the hydrophobic macroporous PS/DVB particle with a hydrophilic layer, in much the same way as for aqueous size exclusion applications described above, prior to introduction of the ionic functionality.

Figure 7 Reversed phase ion pair separation of six proteins. Column: PLRP-S 100 nm 8 μm , 150 \times 4.6 mm; eluent: 20–50% aq. acetonitrile with 0.1% trifluoroacetic acid, 0–20 min; flow rate: 1.0 mL min⁻¹; detector: UV, 254 nm. Key: 1, ribonuclease A; 2, cytochrome c; 3, lysozyme; 4, bovine serum albumin; 5, myoglobin; 6, ovalbumin.

Table 3 Useful ion exchange functionalities

Type	Functional group	pH range
Strong cation exchanger	$-\text{SO}_3^-$	> 3
Weak cation exchanger	$-\text{CO}_2^-$	> 8
Weak anion exchanger	$-\text{NH}_3^+$	< 6
Strong anion exchanger	$-\text{NR}_3^+$	< 9

When applying a coating technique the risk of pore in-filling remains, which would reduce both the accessibility and ionic capacity towards large biomolecules such as proteins. A very thin uniform layer is required but problems can arise if small areas of polystyrene remain exposed. These will interfere with the separation mechanism and so strict quality control procedures are required to detect such weaknesses. An alternative approach to increase the surface density of the ionic functionality has been to apply a thin layer of microspheres to the surface of the particle, thus significantly increasing the surface area.

Ion Chromatography

Ion chromatography is a particularly important analysis technique, often used for analysis of inorganic ions in water. It covers an enormous range of application areas and may be considered independently from ion-exchange chromatography. Stationary phases for ion chromatography usually possess a very low level of ionic functionality, perhaps 1% that of conventional ion exchange resins. This is so that a very dilute buffer solution can be used as eluent together with a conductivity or similar electrochemical detector in order to achieve the degree of sensitivity required. Even so, several commercial systems require the use of a suppressor column to reduce the background conductivity of the eluent further and so increase detection sensitivity. Indirect UV detection has also been used but can cause difficulties.

Ion Exclusion and Ligand Exchange

Ion exclusion and ligand exchange chromatography are specialized forms of ion exchange, but where many of the columns used are based on low cross-linked microporous PS/DVB gels. The principal application areas for the two column types are the analysis of organic acids and carbohydrates, respectively. Ion exclusion resins are sulfonated polystyrene particles with a cross-link content of around 4–8%. A very high level of sulfonation is used during manufacture, which renders the PS/DVB matrix hydrophilic. Dilute sulfuric acid is commonly used as the eluent in ion exclusion in order to ensure that the organic acids exist in the fully protonated, neutral

form. The separation mechanism has some size exclusion properties owing to the soft nature of the resin, but the principal mode of interaction is through hydrogen bonding and ionic interactions. Some reversed-phase-type of hydrophobic interactions may also remain. The separation of organic acids by ion exclusion chromatography is illustrated in Figure 8.

Since the stationary phase has such a low level of crosslinker it is usually packed into columns of 7–8 mm i.d. in lengths of up to 30 cm. Even so, the flow rate that can be passed through such columns without generating excessive back-pressure is very low, in the order of 0.5–0.6 mL min⁻¹. The viscosity of water or dilute sulfuric acid is such that the separation is normally carried out at elevated temperature (40–60°C). Some care is needed when performing separations involving certain types of carboxylic acid as it is possible to cause inter- or intramolecular reactions where carboxylic acid groups and hydroxyl groups are both present – dehydration can occur, generating anhydrides and generally interfering with the separation mechanism.

This type of sulfonated polystyrene resin can be further modified to produce media for ligand exchange separations of polysaccharides. By introducing a heavy metal counterion – commonly calcium, lead or sodium – it is possible to introduce a new type of interaction mechanism. The resins still possess size exclusion properties and so the elution order of simple carbohydrates is:

The separation of disaccharides, such as maltose and sucrose, and monosaccharides, such as glucose

Figure 8 Ion exclusion separation of organic acids. Column: PL Hi-Plex H, 300 × 7.7 mm; eluent: 0.005 mol L⁻¹ H₂SO₄; temperature: 55°C; flow rate: 0.6 mL/min; detector: UV, 210 nm. Key: 1, oxalic acid; 2, citric acid; 3, tartaric acid; 4, succinic acid; 5, lactic acid.

Figure 9 Mechanism of interaction for ligand exchange separation of saccharides.

and fructose, is influenced by the degree of interaction of the numerous hydroxyl groups on the sugar molecules with the metal counterion. Each saccharide molecule has a unique arrangement of axial and equatorial hydroxyl groups, which are able to interact through hydrogen bonding to a greater or lesser extent. The interaction mechanism is illustrated in Figure 9.

The separation is further confused by the ability of sugar molecules to exist in an equilibrium state between two anomeric forms (and briefly as the linear molecule). Sugar alcohols are linear and they are able to adopt a flexible conformation, greatly increasing the degree of interaction, and hence retention time, on such columns. Figure 10 shows the separation of carbohydrates by ligand exchange.

Unlike with ion exclusion materials, it is not possible to use sulfuric acid as an eluent otherwise the heavy metal counterion would be stripped and re-

Figure 10 Ligand exchange separation of carbohydrates. Column: PL Hi-Plex Ca, 300 × 7.7 mm; eluent: water; temperature: 85°C; flow rate: 0.6 mL min⁻¹; detector: RI. Key: 1, raffinose; 2, lactose; 3, glucose; 4, galactose; 5, fructose; 6, erythritol.

placed. It is also important to avoid fouling of individual column types with dissimilar heavy metal ions. The same restrictions on flow rate apply to these column types as to their ion exclusion counterparts but, because the risk of side reactions is removed, the temperature for such analyses can be further increased up to 85°C.

Affinity Chromatography

Affinity chromatography relies on the introduction of a suitable ligand onto the surface of the resin. Frequently residual hydroxyl functionality is used to react with epichlorohydrin. This generates epoxide groups on the surface of the stationary phase, which can then be used to react with amines on the ligand molecule where appropriate.

As with other separations performed in predominantly aqueous media, it is important to eliminate nonspecific binding. For this reason PS/DVB materials are not particularly suitable unless coated with a hydrophilic film. Methacrylate resins (as described above) can be manufactured incorporating the epoxide functionality *in situ*; otherwise agarose-type materials are perhaps the most common.

Other Unusual Polymeric Supports

A number of unique polymer-based materials have been introduced in recent years to enable unusual separations to be performed. Many of these materials are covered more extensively elsewhere in this encyclopedia and so are not covered in detail here.

Chiral separations can be considered to be a form of affinity chromatography – the ligand chosen is often chiral itself or otherwise possesses an unusual affinity for another chiral molecule. A further development of this process has been to incorporate a ligand as a template molecule into the monomer mixture during the polymerization process. The ligand is removed during washing and clean-up of polymer particle but a molecular imprint remains that can increase the retention time for these molecules during actual analyses.

Pirkle supports are unusual in the respect that the outer surface of the bead contains a different functionality to the inner surface of the macropores. This is usually achieved by modifying the chemistry of the bead as a whole, but then the outer surface of the bead is further modified using a polymeric reagent or enzyme that is excluded from the pore structure. For very large molecules such as plasmids or DNA, which may be unable to penetrate even the largest pores of polymeric media, separations are still possible by using solid particles. The surface area in comparison

to a macroporous molecule is fractional but by using very small particle diameters it can be increased somewhat to enable a separation to take place. The small particle size results in an extremely high back-pressure, and so column lengths are greatly reduced.

In a move away from particles it has become possible to polymerize the monomer/porogen mixture within the column itself, generating the pore structure in much the same way as particles but resulting in a monolith structure – a rigid polymeric cylinder containing through pores as well as diffusive pores. Columns containing such structures are now commercially available.

Introduction

Porphyrins are cyclic tetrapyrrolic compounds (Figure 1) occurring widely in nature. They are, except for protoporphyrin, the oxidized by-product of the porphyrinogens (hexahydroporphyrins) which are the intermediates in the pathways of haem and chlorophyll biosynthesis.

The analysis and separation of porphyrins not only is important in the fields of chemistry and biochemistry of this important group of tetrapyrrolic pigments but is also valuable in the biochemical diagnosis of human porphyrias, a group of diseases associated with abnormal haem biosynthesis and consequently the overproduction of haem precursors. Since some of the enzymes of the haem pathway are sensitive to certain toxic chemicals, analysis of porphyrin excretion patterns may provide a sensitive indicator of exposure to these toxic chemicals which often results in characteristic and diagnostic metabolic alterations of the pathway.

Figure 2 shows the structures of some of the most commonly analysed naturally occurring porphyrins. High performance liquid chromatography (HPLC) is the best technique for the separation of these and other porphyrins. The resolution achieved by HPLC is far superior to other methods, including thin-layer chromatography and capillary electrophoresis (CE).

The HPLC separation of porphyrins, their important metal complexes and hexahydroporphyrins (por-

Figure 1 Structure of porphyrin macrocycle (Fischer's numbering system). The four pyrrole rings are designated A, B, C and D. The β -positions, which are usually substituted with acetic acid (Ac), propionic acid (Pr), methyl (Me), ethyl (Et) and vinyl (V) groups, are numbered 1–8. The four methine bridges or meso-positions are denoted α , β , γ and δ .

pyrinogens) are described below with particular reference to the choice of columns, mobile phases and methods of detection.

Separation of Porphyrin Methyl Esters

Porphyrins may be separated as the underivatized free acids or as their methyl esters following esterification of the carboxylic acid groups. The choice often depends on the application and the sample matrix in which the porphyrins are extracted.

Although many of the methods reported for the separation of porphyrin methyl esters are by normal-phase chromatography on silica, they are better separated by reversed-phase HPLC. Reversed-phase HPLC provides better resolution and is able to separate the type-I and type-III isomers of hexacarboxyl porphyrin hexamethyl ester, pentacarboxyl porphyrin pentamethyl ester and coproporphyrin tet-

ramethyl ester. Furthermore, the polar porphyrins (e.g. hydroxylated uroporphyrins) which are difficult to elute from normal-phase columns are easily eluted before uroporphyrin from the reversed-phase column because the elution order is the opposite of that encountered in normal-phase chromatography.

Figure 3 shows the separation of a mixture of porphyrin methyl esters by normal phase (A) and reversed-phase HPLC (B). The superiority of the latter is clearly demonstrated. The resolution of normal-phase separation could be improved by using 3- μ m particle size silica, but is still insufficient compared with RP-HPLC.

Separation of Porphyrin Free Acids

Choice of Column

Porphyrin free acids are best chromatographed on a reversed-phase column. Chemically bonded silica

Figure 3 HPLC separation of porphyrin methyl esters. (A) Normal phase (μ Porasil, 300×4 mm, $10\text{-}\mu\text{m}$ particle size); eluent, *n*-heptane–methyl acetate (3 : 2, v/v); flow rate, 1.5 mL min^{-1} . (B) Reversed-phase (Hypersil ODS, 250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); eluent, linear gradient elution from 70% acetonitrile in water to 100% acetonitrile in 30 min; flow rate, 1 mL min^{-1} . Peaks: 1, 2 and 3 = hydroxylated porphyrins; 4, 5, 6, 7 and 8 refer, respectively, to tetra- (copro), penta-, hexa-, hepta-, and octa- (uro) carboxyl porphyrin; I and III denote type-I and type-III isomers; mp = mesoporphyrin; pp = protoporphyrin.

with different hydrocarbon chain lengths, from C_1 (trimethylsilyl groups) to C_{18} (octadecylsilyl groups) have all been successfully used for the separation of porphyrins. A C_{18} column is preferred because it is more stable towards aqueous buffer than a C_1 column. The wide range of base-deactivated C_{18} column packings (e.g. Hypersil-BDS) further improves the efficiency of porphyrin separations and is the column of choice.

Choice of Mobile Phase

The porphyrins derived from the haem biosynthetic pathway are amphoteric compounds ionizable and soluble in both acids and bases. They are therefore

ideal for separation by RP-HPLC in the presence of an ion-pairing agent (e.g. tetrabutylammonium phosphate) or by ionization control with an acid (e.g. trifluoroacetic acid), a base (e.g. triethylamine) or a buffer solution (e.g. ammonium acetate buffer).

The choice of a correct mobile phase is obviously important for achieving an optimal separation. With the increasing use of online HPLC–mass spectrometry (LC–MS), the chosen mobile phase ideally should also be fully compatible with mass spectrometry. The introduction of hybrid electrospray quadrupole/time-of-flight MS allows sensitive and specific analysis of porphyrin free acids by LC–MS. To exploit this capability a mobile phase that is sufficiently volatile and is able to separate the whole range of porphyrins, including the complex type-isomers, is highly desirable. This rules out reversed-phase ion pair chromatography and the use of phosphate buffer. Simple acidic eluent such as 0.1% trifluoroacetic acid–acetonitrile mixtures can be used for the separation of porphyrins. However, resolution of the type-isomers of uro- and hepta-carboxyl porphyrins was not achieved although type-isomers of porphyrins with 6, 5, and 4 carboxyl groups were well separated.

To date, mobile phases containing ammonium acetate buffer provide excellent resolution and column efficiency as well as being fully compatible with

Figure 4 Separation of a standard mixture of porphyrins. Column, Hypersil-SAS (150×5 mm, $5\text{-}\mu\text{m}$ particle size); solvent A, 10% (v/v) acetonitrile in 1 M ammonium acetate buffer, pH 5.16; solvent B, 10% (v/v) acetonitrile in methanol; elution, 30 min linear gradient from 0% B to 65% B followed by isocratic elution at 65% B for a further 10 min; flow rate, 1 mL min^{-1} ; detection, 404 nm. Peaks: 8, 7, 6, 5 and 4 refer, respectively, to octa- (uro), hepta-, hexa-, penta- and tetra- (copro) carboxyl porphyrin; I and III denote type-I and type-III isomers; mp = mesoporphyrin; pp = protoporphyrin.

Figure 5 Separation of porphyrins in the faecal extract of a patient with porphyria cutanea tarda (PCT). Column, Hypersil-ODS (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); solvent A, 10% acetonitrile in 1 M ammonium acetate buffer (pH 5.16); solvent B, 10% acetonitrile in methanol; elution, linear gradient at 1 mL min^{-1} from 10% to 90% solvent B in 30 min, followed by isocratic elution at 90% B for a further 10 min; detection, 404 nm. Peaks: 4-Iso = isocoproporphyrin; pp = protoporphyrin; other peaks are identified as in Figures 3 and 4.

LC-MS operation. This buffer has been studied for the separation of porphyrins in detail and the following conclusions have been drawn:

1. The molar concentration of ammonium acetate buffer in the mobile phase significantly affected the retention and resolution. The optimum buffer concentration is 1 M. Below 0.5 M, excessive retention and peak broadening results, particularly in isocratic elution. At above 1.5 M, rapid elution with the consequent loss of resolution was observed.
2. The retention and resolution of the porphyrins are greatly influenced by the pH of the ammonium acetate buffer. Increasing the pH decreased the retention with loss of resolution. The optimum pH range is between 5.1 and 5.2, although this is column dependent. This pH range is, however, suitable for most reversed-phase columns.

In earlier studies it was shown that the isocratic elution of uroporphyrin I and III from reversed-phase columns was organic modifier specific and, with methanol as the organic modifier and 1 M ammonium acetate (pH 5.16) as the aqueous buffer, excessive retention and peak broadening was observed. The methanol adsorbed on the hydrocarbonaceous stationary phase surface is able to form extensive hydrogen bonds with the eight carboxyl groups of uroporphyrin, thus resulting in long retention and peak broadening. This effect is less significant in the separation of porphyrins with fewer

carboxyl groups. Nevertheless it is best to avoid using methanol as the sole organic modifier in porphyrin separations, especially when uroporphyrin is one of the components to be separated.

Replacing methanol with acetonitrile results in excellent resolution of uroporphyrin isomers within convenient retention times. Acetonitrile, however, is immiscible with 1 M ammonium acetate when its proportion is above 35% in the mobile phase. While acetonitrile–1 M ammonium acetate buffer mobile phase systems are excellent for the separation of porphyrins that can be eluted at up to 30% acetonitrile content (8-, 7-, 6-, 5- and 4-carboxyl porphyrins), they are not suitable for the separation of porphyrins that required a higher proportion of acetonitrile for elution, such as the dicarboxyl mesoporphyrin and protoporphyrin. In order to achieve simultaneous separation of all the porphyrins, therefore, a mixture of acetonitrile and methanol as the organic modifier is required. 1 M ammonium acetate buffer is completely miscible with methanol. A mixture consisting of 9–10% (v/v) acetonitrile in methanol as the organic modifier thus overcomes the hydrogen bonding effect caused by methanol and the solubility problem of 1 M ammonium acetate in acetonitrile. In practice, gradient

Figure 6 Separation of porphyrins in the urine of a patient with congenital erythropoietic porphyria (CEP). Column, Hypersil-BDS C_{18} (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); solvent A, 10% (v/v) acetonitrile in 1 M ammonium acetate buffer, pH 5.16; solvent B, 10% acetonitrile in methanol. The elution programme was: 0 to 20 min, isocratic elution at 100% A; 20 to 36 min, linear gradient from 0% B (100% A) to 8% B; 36 to 46 min, isocratic elution at 8% B; 46 to 56 min, linear gradient from 8% B to 16% B; 56 to 66 min, isocratic elution at 16% B; 66 to 86 min, linear gradient from 16% B to 30% B; 86 to 95 min, linear gradient from 30% B to 38% B; 95 to 108 min, linear gradient from 38% B to 42% B; 108 to 118 min, linear gradient from 42% B to 66% B; 118 to 128 min, linear gradient from 66% B to 75% B; 128 to 138 min, linear gradient from 75% B to 90% B; 138 to 145 min, isocratic elution at 90% B. The flow rate was 1 mL min^{-1} throughout. Detection, 404 nm. Peaks: a = meso-hydroxyuroporphyrin I; b = β -hydroxy propionic acid uroporphyrin I; c = hydroxyacetic acid uroporphyrin I; d = peroxyacetic acid uroporphyrin I. The other peaks are identified as in Figures 3 and 4.

Figure 7 Structures of meso-hydroxyuroporphyrin I (A), β -hydroxypropionic acid uroporphyrin I (B), hydroxyacetic acid uroporphyrin I (C) and peroxyacetic acid uroporphyrin I (D).

elution is carried out by inclusion of 10% (v/v) acetonitrile in each of the gradient solvents, i.e. 1 M ammonium acetate (pH 5.16) and methanol.

Separation of Porphyrin Mixtures by Gradient Elution

The separation of a standard mixture of porphyrins on a C_{18} -bonded RP Column (Hypersil-SAS) with the optimized gradient mixtures of 10% acetonitrile in 1 M ammonium acetate, pH 5.16 (solvent A) and 10% acetonitrile in methanol (solvent B) is shown in Figure 4. The complete resolution of uro-, heptacarboxyl-, hexacarboxyl-, pentacarboxyl- and coproporphyrin isomers and the dicarboxyl meso- and proto-porphyrins required just 38 min.

Figure 5 shows the separation of porphyrins on a Hypersil-ODS column, extracted from the faeces of a patient with porphyria cutanea tarda (PCT). It clearly demonstrates the applicability of the system to biomedical analysis.

Figure 8 Structures of the four type-isomers of uroporphyrin.

The gradient system can be easily modified if the separation of polar hydroxylated porphyrins is needed. The separation of porphyrins, including hy-

Figure 9 Separation of uroporphyrin type-isomers. Column, Hypersil-ODS (250 \times 4.6 mm, 5- μ m particle size); eluent, 13% (v/v) acetonitrile in 1 M ammonium acetate buffer, pH 5.16; flow rate, 1 mL min⁻¹; detection, 404 nm.

Figure 10 Separation of uroporphyrin I and III isomers. Column, Hypersil-BDS C_{18} (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); eluent, 9% (v/v) acetonitrile in 1 M ammonium acetate buffer, pH 5.55; flow rate, 1 mL min^{-1} ; detection, 404 nm.

droxy- and peroxyacid-porphyrins, in the urine of a patient with congenital erythropoietic porphyria (CEP) on a Hypersil-BDS (C_{18}) column with an extended elution programme is shown in Figure 6. The structures of the hydroxy- and peroxyacid-porphyrins are shown in Figure 7.

Separation of 8-, 7-, 6-, 5- and 4-Carboxylporphyrin Isomers

The separation of the type-isomers, especially type-I and type-III isomers, is of diagnostic value. The separation of isomers of porphyrins resulted from the decarboxylation of uroporphyrinogen I and III is important for understanding the biochemistry of this part of the haem biosynthetic pathway. Individual porphyrin isomers are best separated by isocratic elution with an appropriate amount of acetonitrile or acetonitrile and methanol in 1 M ammonium acetate buffer, pH 5.16, as eluent.

Uroporphyrins (Eight COOH)

There are four type-isomers of uroporphyrin, denoted I, II, III and IV by Fischer to show the four ways in which the acetic acid groups (Ac) and propionic acid groups (Pr) arranged around the eight β -positions of the porphyrin macrocycle (Figure 8). The naturally occurring type-I and type-III isomers can be easily separated on an ODS column with 13% (v/v) acetonitrile in 1 M ammonium acetate, pH 5.16, as eluent. The system resolved uroporphyrin I from the III + IV and II isomers but could not separate the III and IV isomers (Figure 9). Alternatively, a base-deactivated ODS column (e.g. Hypersil-BDS C_{18}) is used with 9% acetonitrile in 1 M ammonium acetate, pH 5.55, as eluent (Figure 10), which provides a more rapid separation of the I and III isomers.

Heptacarboxyl Porphyrins (Seven COOH)

There are five heptacarboxyl porphyrins that can be formed by the decarboxylation of uroporphyrin I and III. Heptacarboxyl porphyrin I (7I; Figure 11) is derived from the symmetrical uroporphyrin I and the four type-III heptacarboxyl porphyrins (7a, 7b, 7c and 7d; Figure 11) are formed by the random decarboxylation of one of the four acetic acid groups of the asymmetrical uroporphyrin III.

The complete separation of the four type-III heptacarboxyl porphyrins has not been achieved, although the type-I isomer was easily separated from the type-III isomers. With 28% acetonitrile-methanol (1 : 9 v/v) in 1 M ammonium acetate (pH 5.16) as eluent on a Hypersil-BDS column, the four type-III isomers were resolved into three peaks in the elution order 7c, 7d and 7a + 7b (Figure 12). The four type-III isomers could, however, be completely separated following conversion to the corresponding heptacarboxyl porphyrinogens by reduction (see section on Reversed-Phase Chromatography of Porphyrinogens).

Hexacarboxyl Porphyrins (Six COOH)

The structures of the two type-I (6Iab and 6Iac) and six type-III (6ab, 6ac, 6ad, 6bc, 6bd and 6cd) hexacarboxyl porphyrin isomers are shown in Figure 13. On an ODS column (Hypersil-ODS) with 16% (v/v) acetonitrile in 1 M ammonium acetate, pH 5.16 as mobile phase, the two type-I isomers were well resolved from the most abundant naturally occurring 6ad, but complete separation of the other isomers was not achieved (Figure 14).

Pentacarboxyl Porphyrins (Five COOH)

There are four type-III (5bcd, 5acd, 5abc and 5abd) and one type-I (5I) pentacarboxyl porphyrins (Figure 15). These five isomers have been separated on

Figure 11 Structures of heptacarboxyl porphyrin isomers. Isomer 7I is heptacarboxyl porphyrin I. Isomers 7a, 7b, 7c and 7d are type-III isomers. The letters a, b, c and d denote the position of methyl group (Me), i.e. the position in which an acetic acid group (Ac) has been decarboxylated. Pr represents a propionic acid group.

a Hypersil-BDS column with acetonitrile–methanol–1 M ammonium acetate buffer (4.5 : 40.5 : 55, by volume), pH 5.16, as eluent (Figure 16). The elution order was 5I, 5bcd, 5abc, 5acd, and 5abd.

Coproporphyrins (Four COOH)

The structures of the four type-isomers (I, II, III and IV) of coproporphyrin are shown in Figure 17. All

Figure 12 Separation of heptacarboxyl porphyrin isomers. Column, Hypersil-ODS (250 × 4.6 mm, 5-μm particle size); eluent, 28% (v/v) acetonitrile–methanol (1 : 9) in 1 M ammonium acetate buffer, pH 5.16; flow rate, 1 mL min⁻¹; detection, 404 nm. See Figure 11 for structures and peak identification.

Figure 13 Structures of hexacarboxyl porphyrin isomers. 6lab and 6lac are type-I and 6ab, 6ac, 6ad, 6bc, 6bd and 6cd are type-III isomers. The letters a, b, c and d denote the position of methyl groups.

four isomers were easily separated by reversed-phase HPLC on an ODS column with 26% (v/v) acetonitrile in 1 M ammonium acetate buffer (pH 5.16) as eluent (Figure 18). Rapid separation of coproporphyrin I and III isomers could be achieved by using a mobile phase of 30% acetonitrile in 1 M ammonium acetate buffer (pH 5.16) or employing a Hypersil-BDS column which is less retentive but still maintains the resolution.

Retention Mechanism of Porphyrins in Reversed-Phase Chromatography

The dominant retention mechanism is hydrophobic interaction between the porphyrin side-chain substituents and the non-polar hydrocarbonaceous functions of the stationary phase surface. The relative hydrophobicity of the side-chain β -substituents

of the porphyrins is $\text{CH}=\text{CH}_2 > \text{CH}_2\text{CH}_3 > \text{CH}_3 > \text{CH}_2\text{CH}_2\text{COOH} > \text{CH}_2\text{COOH}$. The relative retention of the porphyrins is therefore dependent on the relative number of hydrophobic substituents available for interaction and is thus dominated by the number of alkyl (particularly methyl) groups present in the molecule. The retention increases with increasing number of alkyl substituents, and the following elution order was observed; uroporphyrin (8COOH), heptacarboxyl porphyrin (7COOH, 1CH₃), hexacarboxyl porphyrin (6COOH, 2CH₃), pentacarboxyl porphyrin (5COOH, 3CH₃), coproporphyrin (4COOH, 4CH₃), mesoporphyrin (2COOH, 4CH₃, 2CH₂CH₃) and protoporphyrin (2COOH, 4CH₃, 2CH=CH₂).

This retention mechanism is also applicable to the separation of type-isomers. For example, the elution order (I, III, IV, II) of coproporphyrin isomers could be explained as follows.

Figure 14 Separation of hexacarboxyl porphyrin isomers. Column, Hypersil-ODS (250 × 4.6 mm, 5- μ m particle size); eluent, 16% (v/v) acetonitrile in 1 M ammonium acetate buffer, pH 5.16; flow rate, 1 mL min⁻¹; detection, 404 nm. phobic surface area available for interaction. The symmetrical coproporphyrin I has no adjacent CH_3 groups and is the least hydrophobic. It is the fastest eluting isomer. Coproporphyrin III and IV each have a pair of adjacent CH_3 groups. In this situation the relative distance between the adjacent CH_3 pair and the remaining two non-adjacent CH_3 groups becomes an important factor in determining the relative hydrophobicity. In coproporphyrin IV, each of the adjacent CH_3 groups is five bonds away from the nearest

Figure 20 Structure of porphyrinogen (hexahydroporphyrin) macrocycle.

non-adjacent CH_3 group. In coproporphyrin III these are five and six bonds apart, respectively. The slightly longer distance (one bond-distance) between one of the adjacent CH_3 groups and its nearest non-adjacent CH_3 group (six instead of five bonds apart) is sufficient to make coproporphyrin III less hydrophobic than and therefore eluted before coproporphyrin IV (Figure 18).

The elution order of the penta- and hexa-carboxyl porphyrin isomers could be similarly predicted. This also explains why it was difficult to resolve the type-III heptacarboxyl porphyrin isomers since the single CH_3 group present in these molecules makes them very similar in hydrophobic surface area. The study of retention behaviour is useful in elucidating the nature of side-chain substituents present in unknown porphyrins.

Reversed-Phase Chromatography of Metalloporphyrins

The most important naturally occurring metalloporphyrins are the Mg, Fe, Cu, Zn and Co complexes of dicarboxyl porphyrins. Iron complexes form the prosthetic groups of the various haemoproteins, Mg complexes are found in the chlorophylls and Co complex in vitamin B_{12} . In heavy metal poisoning, particularly lead intoxication, erythrocyte Zn-protoporphyrin is elevated.

The mobile phases developed for the separation of porphyrins have been modified for the separation of dicarboxyl porphyrins and metalloporphyrins. These highly hydrophobic porphyrins are best separated on the least hydrophobic C_1 -bonded column. Methanol is the preferred organic modifier since the dicarboxyl porphyrins and their metal complexes do not form extensive hydrogen bonds with the methanol extracted into the stationary phase, as with uroporphyrin. Methanol gave better resolution of dicarboxyl porphyrins and their metal complexes and is totally miscible with the 1 M ammonium acetate buffer (pH 4.6) used in the mobile phase. The separation of

a mixture of dicarboxyl porphyrins and metalloporphyrin is shown in Figure 19.

The insertion of a metal ion which completely occupies the centre of the porphyrin hole significantly alters the electronic environment around the central nitrogen atoms. The retention of the metalloporphyrin is therefore dependent on the ability of the inserted metal ion to accept axial ligands from the mobile phase. Co and Fe complexes are good axial ligand acceptors and may add two extra ligands; Zn complex can add one extra ligand, while further coordination of the Cu complex is only possible under special conditions. The addition of polar axial ligands leads to a decrease in the overall hydrophobicity of a molecule and therefore its retention. Thus, the elution order of Co, Fe, Zn and Cu complexes, was observed for both meso- and proto-porphyrins.

The elution order of the Zn and Cu complexes of meso- and proto-porphyrins is the same as that for meso- and proto-porphyrins with the former eluted before the latter. These metalloporphyrins do not accept axial ligands readily and their relative reten-

Figure 22 Separation of pentacarboxyl porphyrinogen isomers. Column, Hypersil-ODS (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); eluent, 40% (v/v) methanol in 1 M ammonium acetate buffer, pH 5.16; flow rate, 1 mL min^{-1} ; detection, amperometric at $+0.70$ V.

tion is still governed by the relative hydrophobicity of the side-chain substituents.

The elution order of the Co and Fe complexes of meso- and proto-porphyrins is the reverse of that observed for Zn and Cu complexes. Co and Fe complexes are excellent axial ligand acceptors. The decrease in electron density at the pyrrolic nitrogens in metalloprotoporphyrins due to the vinyl groups of protoporphyrin is reflected in the chelated metals, leading to increased affinity for the donor electrons of the extra axial ligands. This leads to a decrease in the hydrophobicity of Co- and Fe-protoporphyrins.

Reversed-Phase Chromatography of Porphyrinogens

The porphyrinogens are hexahydroporphyrins (Figure 20). They are the true intermediates in the bio-

synthesis of haem, chlorophylls and vitamin B₁₂. Porphyrinogens are not often separated because they are easily oxidized to the corresponding porphyrins by air and it is mainly the porphyrins which are present in body fluids and excreta. Studies have shown that isomers of porphyrinogens are better resolved than the corresponding porphyrins. The separation of porphyrinogen isomers is therefore important in situation where the separation of porphyrin isomers is incomplete or could not be achieved.

Coproporphyrinogen, Penta-, Hexa-, Hepta-carbonyl Porphyrinogens and Uroporphyrinogen Isomers

The complete separation of coproporphyrinogen I, II, III and IV isomers could be achieved in 15 min on an ODS column with 25% (v/v) acetonitrile in 1 M ammonium acetate buffer (pH 5.16) as mobile phase (Figure 21). Porphyrinogens are more flexible compounds than the rigid porphyrin macrocycles. In the flexible coproporphyrinogen molecules, the small CH₃ substituents in each isomers may be subjected to varying degrees of steric hindrance or shielding by the larger propionic acid groups, depending on the adopted conformation. This alters the expected available surface area for hydrophobic interaction and makes prediction of elution order based on hydrophobic interaction by the methyl group difficult. The conformation of porphyrinogens under reversed-phase conditions have not been studied.

The superior separation of porphyrinogens compared with porphyrins was similarly observed for penta-, hexa- and hepta-carboxyl porphyrinogens

Figure 23 Separation of hexacarboxyl porphyrinogen isomers. Column, Hypersil-ODS (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); eluent, acetonitrile-methanol-1 M ammonium acetate (8 : 12 : 80, by volume); pH 5.16; flow rate, 1 mL min^{-1} ; detection, amperometric at $+0.70$ V.

Figure 24 Separation of heptacarboxyl porphyrinogen isomers. Column, Hypersil-ODS (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); eluent, acetonitrile–methanol–1 M ammonium acetate, (7 : 3 : 90, by volume) pH 5.16; flow rate, 1 mL min^{-1} ; detection, amperometric at $+0.70\text{ V}$. (Reproduced with permission from Lim *et al.* (1987) *Biochemistry Journal* 247: 229–232.)

(Figures 22, 23 and 24, respectively). The improvement for the heptacarboxyl porphyrinogens was such that all four type-III isomers could be easily resolved (Figure 24).

For the uroporphyrinogens, there was no improvement in resolution over the porphyrins and a reversal of elution order was observed for the type-I and type-III isomers (Figure 25).

Detectors for Porphyrins and Porphyrinogens

Porphyrins have intense red fluorescence and are therefore easily detected with great sensitivity and specificity with a fluorescence detector set at excitation wavelengths of 400–420 nm and emission wavelengths of 600–620 nm.

Porphyrins have an intense absorption band at about 400 nm (Soret band) with molar extinction coefficients often around 400 000. Detection at the Soret band region with a UV-visible detector also provides excellent detectability.

Porphyrinogens are colourless compounds devoid of fluorescence and with only weak UV absorptions at the 220 nm region. They are best detected electrochemically by the oxidation mode because of the ease of oxidation of these compounds.

In terms of sensitivity and specificity, the mass spectrometer is the ‘detector’ of choice. Online LC–MS, especially with electrospray quadrupole

time-of-flight MS–MS, allows porphyrins, metalloporphyrins and porphyrinogens to be detected and characterized with ease.

Figure 25 Separation of uroporphyrinogen I and III isomers. Column, Hypersil-ODS (250×4.6 mm, $5\text{-}\mu\text{m}$ particle size); eluent, 6% (v/v) acetonitrile in 1 M ammonium acetate buffer, pH 5.16; flow rate, 1 mL min^{-1} ; detection, amperometric at $+0.70\text{ V}$.

Future Developments

There are two areas in porphyrin separation which are expected to develop further in the future. The first is in column technology. The improvement achieved by the introduction of base-deactivated reversed-phase is expected to continue and better columns with improved resolution and reproducibility can be expected. The second is in online LC-MS-MS operation. With the introduction of high sensitivity and resolution mass spectrometers, analysis of porphyrins will be a lot easier in the future.

POWDERED RESINS: CONTINUOUS ION EXCHANGE

process incorporated ion exchange and filtration into one unit operation.

Introduction

The use of finely divided (powdered) forms of ion exchange resins began in the early 1960s. Prior to that, synthetic ion exchange resins were manufactured as granules, or preferably spherical beads. The ion exchange granules and beads were used in packed beds to treat liquids, most commonly water. The Graver Water Conditioning Company pioneered the use of the powdered ion exchange resins made by grinding ion exchange resin beads or granules into powders. They discovered that a thin layer of powdered resin offered a dramatic improvement in ion exchange reaction rate versus a conventional packed bed of resin. In 1966 Joseph A. Levendusky of Graver Water Conditioning patented a powdered resin system (named Powdex®) that has been the basis for most practical applications of this technology. This process utilized a pre-coat of powdered ion exchange resins applied to a septum or filter. Thus, the pre-coat

Basic Principles

The original pre-coats were made by combining powdered anion exchange resin with powdered cation exchange resin in a water slurry. Both types of resin were ground moist (40-60% moisture content) into powders using grinding equipment such as hammer mills. This grinding process resulted in a distribution of particle sizes, typically from 1 to 200 µm in diameter. These distributions were centred in the 35-70 µm range. Thus, the powdered ion exchange particles are roughly two orders of magnitude smaller than conventional ion exchange resins (Figure 1). The grinding process also results in a tremendous increase in surface area and, consequently, a higher surface area to weight ratio.

Particle size of powdered ion exchange resins is the most important factor in determining performance of pre-coats. In these applications, resin particle size influences ion exchange capacity utilization, filtration efficiency, filtration capacity and pre-coat characteristics (integrity, uniformity, lifetime). In their classic paper, Frisch and Kunin elucidated the effects of

Figure 1 Powdered ion exchange resins.

particle size on kinetics (the rate of reaction) and, hence, utilization of capacity for ion exchange resins. Specifically, both exchange rate and utilization are inversely proportional to particle diameter. **Figure 2** illustrates the relationship between particle size and ion exchange kinetics for standard-sized bead, small-sized bead and powdered strongly basic anion resin. Because of their inherently better kinetics, powdered resins typically exhibit equal, or higher, operating capacities to those of bead resin counterparts.

When mixed in water, powdered resin particles of opposite charge flocculate to form a larger, well-defined agglomerate. This agglomerate particle is commonly called a floc. The size of the floc formed

Figure 2 Ion exchange kinetics as a function of particle size. Continuous lines, powdered resin; dashed line, 50-100 mesh; dotted line, 16-40 mesh.

Table 1 Surface charges of powdered resins

Resin type	Ionic form	Zeta potential (mV)
Strongly acidic cation	Hydrogen	-42
Strongly acidic cation	Sodium	-40
Strongly acidic cation	Ammonium	-30
Strongly basic anion	Hydroxide	+48

depends on the surface area and the surface charge of the particles prior to flocculation. The increased surface area resulting from the grinding process explains why powdered resin particles flocculate to a much greater extent than corresponding standard-size resin particles. Electrical charges on the surface of powdered resin particles are measured using zeta potentials. **Table 1** summarizes the zeta potentials for specific ionic forms of common powdered ion exchange resins used in pre-coats.

The flocculated mixture of cation and anion resins has a volume up to 20 times that of the unmixed components in water. As the floc forms, void volume between particles increases dramatically, resulting in this increased bulk volume. Factors, such as the ratio of the two resin components, the ionic forms of the components, the resin slurry concentration, the ionic strength of the solution, the temperature of the slurry and particle sizes of the components and determine the bulk volume of the flocculated mixture.

In addition to their ion exchange capabilities, pre-coats offer excellent filtration. This filtration results from a combination of fine particles (high surface area per unit weight) and significant porosity within the pre-coat. The presence of charged ion exchange sites further enhances the filtration performance. In this regard, the new and freshly regenerated powdered resins found in pre-coats optimize filtration efficiency.

Pre-coat Formulations

The original pre-coat formulations, such as those used in the Powdex® process, were made from just two powdered ion exchange components: a strongly basic anion resin and a strongly acidic cation resin. Typically, these resin components were supplied in the regenerated (ionic) form (H^+ for the cation and OH^- for the anion). These powdered components were added to water and stirred to form a slurry. The bulk volume of the resultant slurry could be controlled by addition of an innocuous organic material, such as dilute polyacrylic acid, which reduces clumping. This organic material binds tightly to the surface of one of the components, typically the anion resin, thus effectively reducing the surface charge of that

component. Use of individual components allows the pre-coat user to adjust the cation to anion ratio according to the requirements of the application. As the technology has evolved, pre-coat manufacturers have offered alternative ionic forms (ammonium, sodium, morpholinium and chloride) and alternative resin chemistry components (weak electrolytes, macroporous exchangers and Type II strongly basic anions) for specific applications.

Premix pre-coats are formulated and tested before shipment to a customer. In contrast to the ultimate flexibility associated with component pre-coats, premixing by the manufacturer guarantees a specific ratio of components and a uniformly mixed material.

In 1976 the first premix incorporating fibre along with the anion and cation resin components was introduced; the corresponding patent was granted 4 years later. Chopped alpha-cellulose fibre was used in this premix and still is the most common fibre constituent in pre-coats. Cellulose fibres are hydrophilic and contain carboxylic groups whose charge facilitates flocculation with resin components. The tendency for fibre flocculation with resin components can be further enhanced by charging the fibre with an ionic polymer with a significant zeta potential. Inclusion of the fibre increases filtration efficiency and minimizes pre-coat cracking caused by the adsorption of colloids on the surface of the anion resin particles. The fibre adds bulk volume and porosity; the amount of bulk depends on the length and rigidity of the fibre: longer and more rigid fibres produce bulky pre-coats and vice versa. A variety of noncellulosic fibres have been used in premixes. Both polyacrylonitrile (PAN) and composite polystyrene/polyethylene fibres are used in current commercial formulations. In the latter case, the polystyrene fibres are functionalized with ion exchange sites, typically sulfonic acid type, to form an ion exchange resin fibre. Fibre can also be incorporated in standard pre-coats via addition as a separate component. Moreover, the fibre can be utilized separately either as an underlay pre-coated prior to the resin components, or conversely, as an overlay pre-coated after the resin components.

Commercial premixes currently popular are available in a variety of component ratios, as shown in Table 2. Pre-coats are formulated on a dry weight basis. Many fibres have virtually no moisture content, while most ion exchange resins contain 40–60% water unless dried. The premixes listed in Table 2 are available with either hydrogen form or ammonium form cation resin. The 4:5 cation-to-anion ratio common to fibre-containing premixes yields a roughly stoichiometric mix of cation and anion exchange sites.

Table 2 Common premix pre-coat compositions

<i>Resin content (dry weight ratio)</i>		<i>Mix content (dry weight ratio)</i>	
<i>Cation resin</i>	<i>Anion resin</i>	<i>Fibre</i>	<i>Resin</i>
1	1	0	1
2	1	0	1
3	1	0	1
4	5	1	1
4	5	1	2
4	5	1	9

Pre-coat Properties

Typically, three properties characterize pre-coats and premixes: moisture content, settling volume and supernate turbidity. Premixes are made from a slurry of the components. The slurry is dewatered by means of centrifugation or a similar mechanical process. The dewatered premix retains water associated with the ion exchange resin sites. Moisture content, or water retention as it is sometimes called, is a measure of the amount of water relative to the solids content of the premix. Typically, moisture contents vary between 50 and 70%. The settling volume measures flocculation of a pre-coat under standardized conditions. The measurements are done in a graduated cylinder with a specific volume and specific concentration of pre-coat slurry. Slurry volume is measured initially and after a specific settling time (t) and calculated according to the following equation:

$$\text{Settling volume } [V/V](\%) = 100 \times (V_t/V_0)$$

Settling volumes typically vary from 40–70%. High settling volumes are indicative of increased pore volume and, consequently, bulky pre-coats, while low settling volumes are indicative of ‘tight’ pre-coats. As the settling volume increases, depth filtration improves, but ion exchange efficiency tends to decline. Turbidity is measured on the supernatant at the conclusion of the settling volume test. Turbidity is recorded in nephelometric units (NTU): values below 10–15 NTU are considered acceptable. Low turbidity values are indicative of full incorporation of pre-coat components. Typically, anion resins generate more very small particles than cation resins during the grinding process. These fine anion resin particles, in turn, are the least likely to be fully flocculated in the pre-coat and consequently cause turbidity. Fibres are another potential source of turbidity. Fibre particles have weaker charges than resin particles and thus prove harder to flocculate fully in a pre-coat. Fortunately, the addition of the correct amount of the properly charged dilute polyelectrolyte (e.g. polyacrylic acid or polyacrylamide) usually flocculates these

unincorporated particles and dramatically improves turbidity. Thus, turbidity measurements assist manufacturers in formulating premixes and users in preparing pre-coats satisfactorily from components.

The American Society for Testing and Materials (ASTM) has published validated test methods for measuring properties of the powdered ion exchange resins used in pre-coat materials. Specifically, Standard D 4266-83 covers measurement of the operating capacity for both powdered cation exchange resins (either hydrogen or ammonium form) and powdered anion exchange resins (hydroxide form). Similarly, Standard D 4456-85 encompasses determination of particle size distributions and solids content for powdered ion exchange resins (see Further Reading).

Pre-coat Equipment

Before the introduction of powdered ion exchange resins, materials such as diatomaceous earth and cellulose fibres were coated on to leaf filter elements or wire screen septa. While both these materials and this type of equipment are still used in pre-coat operations, the use of powdered ion exchange resins in

pre-coats has led to equipment modifications and improvements.

The basic equipment used for pre-coating with powdered ion exchange resins is fairly simple: a tank for mixing powdered components into a slurry and a filter or septum suitable for retaining the slurry solids. In addition to these basic components, pumps, piping, valves and instrumentation are used in virtually all pre-coat systems. **Figure 3** is a schematic drawing of a typical system used in commercial applications. Vessels used for pre-coating operations generally contain an array of tubular filter elements or septa. These arrays fall into two major designs: top tube sheet and bottom tube sheet. **Figures 4** and **5**, respectively, are schematic drawings of these two designs. The term 'tube sheet' refers to the support structure to which the individual elements are attached. Top tube sheet elements originally were designed to use stainless steel wire cloth or well screen elements. These metal elements have relatively large diameter (0.075–0.150 mm) openings. Bottom tube sheet elements typically use continuously wound yarn elements with much smaller openings (nominal ratings of 0.001–0.010 mm). These filter elements come

Figure 3 Typical pre-coat system schematic.

Figure 4 Pre-coat system design: top tube sheet.

in a variety of diameters and lengths; large vessels accommodate 127–203 cm elements. A variety of fibres, including polyester, polypropylene, nylon and carbon, are used for the yarn winding, depending on the application.

It should be noted that powdered resin pre-coats can be applied to traditional septa such as leaf filters or plate and frame filter presses. Resin pre-coats can also be used in beds in columns similar to bead resins. This type of usage is typically limited to small bed depths due to hydraulic considerations (pressure drop across the bed).

Operation

The slurry tank is filled with water, preferably de-ionized. Individual powdered components or a premixture of the same are weighed out, added to the water and mixed using a mechanical stirrer. Generally, dosage rates of the pre-coat vary from 0.73 to

1.46 dry kg pre-coat per square metre of surface area on the septum. This dosage will result in a pre-coat of 0.63–1.27 cm depth. Recently, thin-layer pre-coats have become popular with dosage rates of 0.24–0.49 dry kg m⁻². Overlays and underlays are often pre-coated at even lower dosage rates of 0.10–0.24 dry kg m⁻².

The pre-coat is applied to the filter or septum as a slurry via the pre-coat pump at an area flow rate of 0.68–1.70 L s⁻¹ m⁻². The slurry concentration as it enters the pre-coat vessel is critical. A concentration of 0.05% is ideal, though not always attainable. The pre-coat recycle loop shown in Figure 3 is used to optimize slurry concentration entering the pre-coat vessel through dilution. The objective is to lay down a uniform pre-coat across the length of each and every filter element. A low slurry concentration will translate into small floc size. The small floc, in turn, can be carried to the upper portion of the vessel despite low flow in that region. Alternatively, larger floc particles

Figure 5 Pre-coat system design: bottom tube sheet.

can reach a point where the flow carrying them upward is balanced by gravity. The consequence of this condition is reflocculation where floc grows in size, then falls towards the bottom. Even if the refloc eventually pre-coats the filter, its large particle size

creates an uneven surface. Pre-coating, along with recirculation, continues until all powdered material is deposited on the surface of the filter elements. This process takes 10–90 min, after which additional recirculation allows the system to clear (residual turbid-

ity in water dissipates). At this point, the pre-coat is ready for standby or service. If the standby option is chosen, the hold pump maintains sufficient flow across the pre-coat to prevent it from falling off the filter element. In some instances, application of additional pre-coat material – a technique known as body feed – during the service cycle greatly enhances system performance.

During the service cycle, the pre-coat removes contaminants from the feed solution via ion exchange, adsorption and filtration mechanisms. The purified solution passes through the pre-coat and the filter element and emerges as product. Water quality, usually measured by conductivity and/or ionic content, and pressure drop across the pre-coat are monitored throughout the service cycle. During the service cycle, the pre-coat contracts and tightens as it is loaded with ions, organics and colloids. The area flow rate during the service cycle is $2.0\text{--}2.7\text{ L s}^{-1}\text{ m}^{-2}$. Deterioration of one of the measurement parameters determines the end point of the service cycle (e.g. differential pressure drop across the pre-coat increases by 0.70 kg cm^{-2}). At this point, the expended pre-coat is removed from the filter via back-wash. During back-washing flow across the pre-coat is reversed and the solids are slurried to waste. With the evolution of pre-coat technology, back-washing has also changed from simple surges of water or air to combinations of high pressure air and water. The scrubbing properties of the air and water combination are further enhanced by repeated applications, each with a different level of water in the pre-coat vessel. The greatest effect occurs on the element in the immediate vicinity of the air–water interface in the vessel. These elaborate processes are designed to remove pre-coat particles embedded in the filter element as well as the bulk pre-coat on the surface. At the conclusion of the back-washing steps, the system is ready for the next pre-coat.

Over the years, mechanical innovations have improved upon the original pre-coating process. Metering tanks feed the resin slurry into the mix tank at a specific rate, thus offering excellent control over slurry concentration. Draft tubes installed in the pre-coat vessel carry pre-coat particles directly from the inlet at the bottom of the vessel to the top of the vessel. With the draft tube design, slurry flow is split and the filter elements are exposed to pre-coat flow both top-down and bottom-up. The result is a more even pre-coat deposition on the element.

Applications

Powdered pre-coats have been useful in a wide variety of applications. Among the most common are polish-

ing steam condensates; treatment of low activity radioactive wastes; decolorization, decalcification and clarification of sugar juices, sugar syrups and polyhydric alcohols; clarification of fluids containing electrolytes and colloids; purification of antibiotics, vitamins and other pharmaceuticals; removal of toxic and noxious organics from potable and industrial waters; recovery of precious metals; pretreatment of high purity water systems; recovery of catalyst residues from reaction mixtures; and removal of traces of acids, bases and salts from polar solvents. Most pre-coat applications involve removal of impurities present in low concentrations.

Powdered ion exchange resin pre-coats were first utilized in electric power plants. Originally, bead-form ion exchange resins were used to remove (polish) soluble ionic contaminants from condensate prior to recycle to the steam generators. Powdered resin pre-coats combined this ion exchange polishing capability with filtration of colloidal and particulate materials such as a mixture of transition metal oxides (Fe, Cu, Co, etc.) present in steam condensate due to erosion or corrosion. Pre-coat technology was applied in both nuclear and fossil steam-generating plants. This technology proved particularly valuable in the boiling water reactor (BWR)-type nuclear plants. Unlike their bead counterparts, powdered pre-coats generate no liquid waste regenerants since they are designed to be nonregenerable and disposable solids. Issues such as short run lengths due to the high level of suspended solids in BWR condensate led to the development of pre-coats incorporating fibre in addition to powdered resins. The use of powdered resins in nuclear condensate polishing is so prevalent that operational guidelines have been issued by the US industry (see Further Reading).

In addition to condensate polishing, powdered pre-coats are used in reactor water clean-up (RWCU), elevated temperature heater drain and fuel pool purification applications in nuclear power plants. Powdered pre-coats have also been widely adopted in nuclear power plants for radioactive waste systems. In these systems, the powdered resin materials are pre-coated directly on to existing filters replacing diatomaceous earth or cellulose fibres. They offer both efficient ion exchange capacity and corrosion product filtration. These pre-coat materials have been tailored to remove specific troublesome radionuclides with a long half-life such as ^{60}Co , ^{90}Sr , ^{134}Cs and ^{137}Cs . In addition to synthetic organic ion exchange resins, both natural and synthetic zeolites are utilized in selective radioactive waste applications. Similarly, alternative resin types such as ammonium form or morpholinium form strongly acidic cation and weakly acidic cation components

are commercially available to customers from public utilities.

Blaine and Down first described the application of powdered ion exchange resin technology for decolorizing sugar syrups. Colour bodies in sugar syrups are high molecular weight entities which anion exchange resins typically selectively remove. Blaine and Down reasoned that reaction kinetics, as controlled by particle diffusion, are much slower in viscous liquids such as sugar syrups than typically found in water applications. Consequently, finely divided powdered resins decolorize much more rapidly than their larger bead counterparts. Moreover, the powdered resins are used as disposable, non-regenerable filter pre-coats, thus eliminating the need for chemical regenerants for the ion exchange resin. These pre-coats offer increased operating capacity for colour removal without generating unacceptably high pressure drop across the pre-coat. The high decolorization capacities also result in lowered sugar losses from dilution during the sweetening-off and sweetening-on steps. Sugar pre-coats offer clarification through filtration in addition to decolorization.

The initial sugar decolorization pre-coats contained mixtures of anion and cation exchange resins. Over the years, commercial formulations have expanded to include mixtures of selective anion exchange resins, powdered activated carbons and/or chopped fibres depending on the specific application. These formulations are tailored for the clarification and decolorization of sugar syrups (cane, corn and beet), fruit juices (grape, apple) and polyhydric alcohols (glycerine, sorbitol). The decolorization performance of these pre-coats compares favourably with traditional technologies (bone char, granulated activated carbon and regenerable ion exchange resins), especially as a final polishing step. In addition, tailored pre-coats remove species that cause undesirable taste and odour in the product. Pre-coats also offer limited de-ashing (deionizing) capacity in sugar syrups. De-ashing is limited by the number of ion exchange sites, not to mention the competition from colour bodies for the anion exchange sites. Low capital investment, limited space requirements and reduced energy costs are cited as advantages for the pre-coat technology in sugar applications.

Future Directions

Powdered pre-coat usage has been declining in recent years, especially in utility applications. Few new power generation plants are designed and built with pre-coat systems. In nuclear power plants, the cost of

radioactive resin disposal continues to rise dramatically. Thus, utilities have minimized the use of ion exchange resins, including powdered pre-coats, in these facilities. The introduction of thin-layer pre-coat technology has further accelerated this trend. Because of the risk of leaching after burial, concerns are increasing over the ultimate fate of formulations containing biodegradable fibres such as cellulose. Fortunately, alternative fibres such as PAN, nylon, polyethylene and polyester fibres can be substituted for the cellulosic fibre in pre-coat formulations. The PAN fibre formulations offer the added advantage of extended run length to a given differential pressure drop end point. Pleated filter elements have replaced yarn wound filter elements in many plants. The pleated elements offer excellent iron removal without using a powdered pre-coat.

Premix pre-coats are increasingly popular, replacing traditional powdered component pre-coats. Premixes offer the convenience of a one-step operation and do not necessitate operator adjustments during pre-coating. Of course, the flexibility of adjusting powdered component ratios on each cycle depending on influent conditions is lost with premixes. As available human resources (operators) shrink, the popularity of premixes will continue to grow. Customers demand and receive ultrahigh purity powdered pre-coats. Specification limits on residual contaminants such as iron, copper, aluminium, silica, sodium, potassium, calcium and magnesium for powdered pre-coats are typically set at 50 p.p.m., 25 p.p.m. or even 10 p.p.m. by dry weight. These stringent specifications apply to both resin components and pre-coat formulations. Increasingly, selective ion exchange media, including zeolites, are being incorporated into pre-coat formulations. Radioactive waste applications, discussed above, are a perfect example of this trend. Custom-designed powdered pre-coats of all types are growing in popularity.

PREPARATIVE ELECTROPHORESIS

R. M. C. Sutton and A. M. Stalcup,
University of Cincinnati, Cincinnati, OH, USA

Introduction

The development of electrophoresis in the early part of the 20th century proved to be an extremely important tool for the separation of biologically important molecules such as amino acids, peptides, proteins and DNA. There are four main types of electrophoresis, known as zone electrophoresis, step-field electrophoresis, isoelectric focusing and isotachopheresis. This review discusses the development of zone electrophoresis and step-field electrophoresis for preparative applications.

Electrophoresis instruments use mobility differences in the presence of an electric field to separate mixtures into individual components. The mobility differences between individual species are proportional to the net charge to size ratios of the species. Therefore, separations are most effective for solutes with large differences in this ratio. Additional separation mechanisms, such as molecular sieving using gels, have since been incorporated in the modes of electrophoresis to increase the range of applicability. At present, there are a wide range of electrophoresis instruments and methods which are used routinely in the biotechnology industry for analytical measurements. In contrast, the use of preparative electrophoresis is far less extensive.

The major distinction between analytical and preparative electrophoresis lies in the size and processing of samples. In the case of preparative electrophoresis, sample sizes are generally much larger (mg to g) in comparison with analytical electrophoresis (ng to µg) depending on the availability of the species of inter-

est. Such large samples must not be too crude because irreversible adsorption of some unwanted species can render the system inoperable. The samples also require the collection of fractions after separation, which is often not the case with analytical separations. Thus, after separation, it is essential that the solutes can be easily removed from the buffer solution if they are to be prepared as pure compounds. The constitutions of buffer solutions must therefore be carefully chosen, preferably with volatile components, which facilitate collection of the species of interest.

Preparative electrophoresis systems require scaling up from the respective analytical systems and modifications to the instrumentation have been made which attempt to contend with complications arising from the scale-up. For instance, an inherent problem with electrophoresis is thermal convection caused by the flow of ions in the presence of an applied electric field. As electrophoresis systems are scaled up for preparative applications, convection problems and heat dissipation in the system become more significant owing to the decrease in the relative surface area. Anticonvective media such as filter paper, agarose, starch, glass powder or polyacrylamide have been used to limit these convection processes. The use of anticonvective media, however, has led to other problems, such as adsorption, endosmosis and diffusion. These combined factors have therefore prompted the development of a number of different designs of preparative electrophoresis systems that are suitable for continuous or batch-wise separations of multicomponent mixtures. Two basic strategies have evolved which are collectively termed preparative free-flowing electrophoresis or preparative gel electrophoresis. Both strategies exploit the same basic electrophoresis process for the separation, although both approaches have been used in a variety of configurations.

Preparative Free-flowing Electrophoresis

In the case of free-flowing electrophoresis, there is no anticonvective medium. Separation of samples therefore occurs in free solution and sample zone broadening, as a result of convection, tends to be more pronounced than in the analogous gel method. A support, such as paper, may be used for the buffer to flow across and is cooled to maintain maximum thermal stability in the system. One method of reducing convection processes in the system is to perform the investigations in a cool room (e.g. at 5°C). Such temperatures also ensure that there is no degradation of heat-sensitive samples.

Early reports of free-flowing electrophoresis were first made by Barrolier who devised a continuous separation process. A system was developed in which an electric field was applied perpendicularly to the direction of the buffer flow. Sample was introduced as a constant stream into the top of the system which travelled in the same direction as the buffer. As in the case of other electrophoresis systems, differences in the charge to size ratios of the solutes caused mobility differences in the presence of an electric field. This, in turn, brought about movement of the solutes perpendicularly to the pumped buffer flow, leading to a lateral separation between the two electrodes. Separators at the end of the support facilitated collection of the sample streams into pure fractions (Figure 1). The system was found to be suitable for a series of highly mobile dyes, but convection in the system made it more difficult to separate more complex samples.

A more drastic approach to suppress thermally induced density gradients contributing to convection has been to perform electrophoresis experiments in space. The microgravitational fields in orbiting spacecraft provide a suitable environment for reduced convection in electrophoretic processes.

An alternative design for free-flowing electrophoresis apparatus was developed by Dobry and Finn: this utilized upward movement of the buffer and samples. In this apparatus, electrodes were separated from the system by means of semipermeable membranes placed perpendicularly to the cylindrical electrophoresis chamber. This caused differences in the direction of migration of the solutes, perpendicular to the direction of the buffer flow, and a range of dyes was successfully separated. On separation of the solutes, a series of outlet ducts at the top of the apparatus enabled collection of the purified species. Unfortunately, this early apparatus also appeared to have problems with convection because an effective cooling system was absent. This inferred the occurrence of a temperature gradient within the system, which would affect slower-moving protein mixtures more significantly.

It was not until recently, however, that the approach of reducing convective processes in free-flowing electrophoresis has been made simpler and more effective. This new approach has been labelled capillary free-flow electrophoresis. A coolant solution is continuously passed through a number of evenly spaced Teflon capillary tubes within the separation chambers and has been found considerably to reduce convection processes in the electrophoresis system

Figure 1 A free-flow electrophoresis system. The direction of buffer flow is indicated by 1 and 2. Sample enters continuously at 3 and purified solutes are collected at the vials at position 4.

Figure 2 Design of capillary free-flow electrophoresis system. Cooling water enters at 1, passes through a series of parallel Teflon tubes (number reduced for simplification) and exits at 2. Buffer enters at ports 3–6 and sample stream enters at 7.

(Figure 2). The coolant tubes have not been found to affect the quality of separations adversely. As in the case of previous free-flow systems, the sample is continuously introduced into the system. Therefore the potential for the purification of large quantities of solutes is available (e.g. 1 g h^{-1}).

A more complex-free flowing electrophoresis instrument was designed by Hjertén to address the problem of convection. An apparatus was constructed in which the buffer flowed through a straight horizontal tube, which was rotated axially at constant velocity. The rotating tube alleviated the effects of gravitational convection and sedimentation. Although this system appeared suitable for analytical separations, convection was still a problem with regard to the quantities used for preparative use. The addition of anticonvective media, such as a density gradient, formed using sugar solutions, or the use of a gel was still required. This instrument was in fact the precursor of the capillary electrophoresis instrument.

Another unique approach to free-flow electrophoresis utilized a fluid endless belt. This design is analogous to a small conveyor belt in the vertical position. Movement of the solutes around the belt reduces convection and sedimentation processes occurring in the system. The sample is introduced as a continuous stream close to the electrode from which the solutes are repelled and are collected from the other side of the system, close to the electrode to which they are

attracted. All solutes must, however, be attracted to the same electrode. The solutes travel around the belt several times during the electrophoresis process, moving approximately perpendicularly to the electric field. Solute with the highest mobilities travel farthest across the belt and the separated solutes are collected at the outlets.

Preparative Gel Electrophoresis

The incorporation of gels as a solid support assists in the prevention of convective distortion of the analyte zones. Another advantage of using gels is that there may be an additional effect of molecular sieving which can be exploited to enhance the separation of solutes such as proteins. As a result of these considerations, a number of different gel types have been developed for preparative electrophoresis systems.

One of the first designs of a preparative gel apparatus developed by Hjertén used a starch gel in the form of a horizontal slab. One of the main differences between this system and the free-flowing systems was that sample introduction was not continuous. Using this system, separation of milligram quantities of lysozyme and β -lactoglobulin was achieved over periods of about 40 h.

Another type of gel that has been used with success is agarose. Agarose has been found to be a better support than agar, owing to its purity, and displays very little electroendosmosis. Agarose also displays

little adsorption of proteins and therefore migration of solutes is similar to that in free solution.

The greatest number of investigations using preparative gel electrophoresis, however, has been with polyacrylamide-based gels. A significant advantage of using polyacrylamide gels is that pore radii (between 0.5 and 3.0 nm) can be easily controlled by adjusting the acrylamide concentration and the concentration of the cross-linking agent. As with analytical procedures, gel buffer pH and ionic strength as well as electrode buffer pH and ionic strength must be considered before separation.

A popular method of preparative separation is to use polyacrylamide with detergent in the buffer. Ryan *et al.* modified a preparative polyacrylamide gel for use with systems containing the anionic detergent sodium dodecyl sulfate (SDS). As in analytical gel electrophoresis, addition of the SDS allows separation based on the molecular weight of the solutes. The preparative gel method used was essentially that of Laemmli. This type of system has been found to be suitable for a large number of applications listed in the literature.

Early development in the use of polyacrylamide gels for preparative electrophoresis was stimulated by the development of discontinuous or disc electrophoresis by Ornstein and Davis. Disc electrophoresis enables sharpening of sample zones by using variable conditions within the electrophoresis system. Discontinuities in the separation system are achieved by incorporating different buffer compositions or the same buffer composition at different pH throughout the gel and/or by using voltage gradients during electrophoresis. One of the main features of disc electrophoresis is a concentrating step, which ensures that the sample is compressed into an extremely thin band before electrophoretic separation of the solutes. This type of gel usually consists of three components. The largest portion is the separating gel, which is preceded by a spacer gel and then a small mixture of the sample, in either gel or viscous solution. Lewis and Clark described such a system for the preparative separation of components from rat pituitary glands.

Another variant of disc electrophoresis employs the sequential use of two buffer systems at different pH. A pH close to the isoelectric point of one species is chosen to effect separation initially. This enables migration of one species whilst the other species moves very little. After separation of the two species, the pH of the buffer solution is changed, which causes a rapid increase in the mobilities of both species. Both species are continuously eluted from the gel where they can be detected followed by suitable fraction collection. This approach was found to resolve two forms of phosphoproteins successfully.

Gel Configurations

Since the initial introduction of preparative gel electrophoresis systems in the early 1960s, a range of different instrument designs have also been developed to incorporate gels. Some systems have used glass and others have used LuciteTM (Perspex) for mechanical support of the gel. An advantage using glass is that it has higher thermal conductivity than Perspex, but it has been found that, as the walls become narrower, surface effects from glass become enhanced. In contrast to free-flowing electrophoresis, the use of anticonvective media in these systems allows for magnetic stirrers to be used in the buffer reservoirs. These maintain uniform concentration of buffer components and also prevent bubble trapping. The units have mainly been either cylindrical or slab-like and electrophoresis has been performed in either a vertical or horizontal orientation. In the case of cylindrical gels, gel column heights are important and mainly depend on the diameter of the column used and the sample loading. Improvements in the vertical column cylindrical gel systems have been made by addition of direct cooling. Convection processes have also been reduced by forming the gel around a central cooling capillary. In these cases, elution buffer can be utilized to carry samples to a UV detector before fraction collection and also to cool down the gel as it passes through the central capillary.

A preparative gel apparatus developed by Hediger used a completely sealed system. External buffer reservoirs were used for the electrode and elution buffer. The gel was placed between two adapters in a vertical cylinder. The upper adapter, which was easily movable since it was motor-driven, had a gel-pouring device, which enabled easy preparation of both gradient and nongradient gels.

Slab gels can be run in a vertical or a horizontal position and were initially designed in order to increase the amounts of sample that could be handled in one electrophoretic run. It is not clear whether slab gels offer improved separations over cylindrical gels, owing to the problems associated with cooling and fraction collection in comparison with the column gels.

Hjertén developed a large-scale system that involved a vertical slab gel. This apparatus enables the separation of up to 1 g of material. After elution from the separation chamber, the solutes enter a granular bed of agarose spheres. They are then displaced from the granular bed by a buffer flow, which transfers them to a fraction collector. The system has been used effectively for the separation of a series of proteinases.

The development of an annular-shaped electrophoresis apparatus by Southern enabled a larger

surface area of the gel to be utilized when compared to gels of conventional geometry. The outer electrode is wrapped around the gel and the inner electrode runs on a bobbin on the inside. A rapid flow of buffer passes between a semipermeable membrane and the central electrode to facilitate cooling of the gel. Sample is introduced into a small slot that runs around the periphery of the gel annulus. The material moves from the outside of the gel in concentric circles towards the centre, where it is eluted. Solutes are therefore moving from a large area to a much smaller area, which enables the use of high sample loads. In this case, the fraction volume was kept to a minimum by employing discontinuous elution. The electronics for this system were later modified so that, after electrophoresis was stopped, the current was reversed for a short period of time to remove solutes adsorbed on to the semipermeable membrane surrounding the electrode, before eluting the purified samples from the gel.

Sample Recovery using Preparative Gels

In contrast to free-flow electrophoresis, where sample collection is performed during electrophoresis, preparative gel electrophoresis allows samples to be collected after electrophoresis. Also, most preparative gel electrophoresis is performed as a batch process. There are two methods for recovering the purified samples when using preparative gel systems. Solutes can either be recovered from the gel after the electrophoretic separation, or eluted from the gel during electrophoresis and collected sequentially. In the first case, solutes can be recovered from the gel mechanically (analogous to thin-layer chromatography) or by using electro dialysis. In one example, using polyacrylamide gel columns, samples were cut from the gel using a jig. This method enabled sections to be cut reproducibly from subsequent gels.

The second recovery mode involves electrophoretic migration of analytes from a cylindrical gel using a continuous elution system. As electrophoresis proceeds, the end of the gel is continually flushed with a buffer solution and solutes are transported from the gel. This enables samples to be detected as they leave the system using some form of online detection. After detection, a fraction collector can be used to establish the integrity of the purified samples. An important part of the design of the continuous elution system is a dialysis membrane which is usually placed between the end of the separation gel and the bottom buffer solution. This membrane prevents migration of the solutes into the main buffer solution. For continuous elution systems, elution buffer pH and ionic strength must also be considered.

Figure 3 Side-arm apparatus. The top gel is 1 and the bottom gel is 2. The arrows indicate the elution buffer flow collecting solutes.

A variant of the continuous elution recovery system employs continuous elution from between two gel column halves. A dialysis membrane, placed on top of the bottom gel, ensures complete elution of the solutes as they reach the end of the separating gel. The assembly consists of a 2 cm outer diameter glass tube with two side arms through which buffer is pumped (Figure 3). A system of this type was effective for the separation of a series of bean leaf proteins.

Another method of collecting solutes, after electrophoresis, has been developed and is known as discontinuous elution. Electrophoresis is stopped for short periods of time whilst solutes which have passed through the gel are collected from a cup at the bottom of the gel. This method is believed to reduce dilution of the samples in comparison with continuous elution systems. After removing the solutes and buffer solution from the cup, the cup is refilled with fresh buffer solution and electrophoresis is reinitiated.

Discontinuous sample collection may be fairly time-consuming owing to the intermittent sample collection process. This was one of the reasons that led to the development of automated preparative gel electrophoresis systems. One such system was designed by Hodson and Latner. After a period of time, electrophoresis in the system is stopped and buffer, containing solutes which have passed through the gel, is collected and the buffer chamber refilled. Up to

300 mg of protein mixtures may be separated using the system, with the potential for further scale-up.

Another discontinuous sample collection system, for use with slab gels, has been developed by Polsky *et al.* An electronic timer was used which controlled the collection of samples and refilling of buffer in the elution chamber. Electrophoresis was terminated during collection of the samples. Polyacrylamide slab gels were found to have much higher sample capacities than agarose gels. Two practical considerations concerning the buffer solution were made during this work because of run times exceeding 100 h. Chloride-free buffers were used to prevent build-up of chlorine gas and sterile solutions were used: these inhibit growth of bacteria in the system. The system was effective in resolving and collecting fragments of genomic DNA.

Buffer Types

In accordance with analytical electrophoresis, a wide range of buffers is also available for preparative electrophoresis. Essentially, the type of buffer used in the system depends on the type of sample to be separated and on the type of separation system used. High ionic strength buffers can cause significant Joule heating in a system, whereas low ionic strength buffers may cause protein aggregation.

Detection

One of the main differences between analytical and preparative electrophoresis is that quantitative detec-

tion of solutes is not as critical. This enables cruder detection methods to be used in preparative work. These detection systems can be used in real time with online detection or, in the case of some noncontinuous elution systems, after the separation has finished.

In continuous elution systems, factors which are important in terms of sample detection are the elution buffer flow rate and the elution buffer fraction volume. High elution buffer rates can cause the solutes to become too dilute for the method of detection. Slow buffer rates may cause loss of resolution between the solutes owing to diffusion. One of the most popular forms of online detection is ultraviolet-visible spectrophotometry. Not all solutes absorb or fluoresce in this region of the spectrum, but detection can be achieved in some cases using dye-staining methods. Offline detection includes light scattering, radiography, densitometry, analytical gel electrophoresis and mass spectrometry.

Commercially Available Systems

A number of preparative electrophoresis systems were available in the early 1960s but, owing to lack of demand, are no longer available. This is probably a result of increased competition from other preparative methods such as high performance liquid chromatography.

A large preparative free-flow electrophoresis system was developed at the Harwell Laboratory of the UK Atomic Energy Authority, known as the Bio-stream separator. This was a large apparatus in which

Figure 4 Bio-Rad Mini Prep-Cell.

Figure 5 Separation of piperoxan enantiomers using the Mini-Prep Cell.

laminar flow conditions were maintained by rotation of the outer wall of the annulus. Although allegedly being capable of preparing 100 g h^{-1} of protein, it never became readily available on the commercial market.

Bio-Rad Laboratories (Hercules, CA) currently have several preparative gel electrophoresis systems for use with gels (**Figure 4**). These are continuous elution devices based on vertical column gels. One of the larger systems has a ceramic core that is used for cooling the gel.

A capillary free-flow electrophoresis system has been patented by R&S Technologies. The device is believed to be considerably better than previously produced free-flowing electrophoresis systems owing to reduced convection in the system from the capillary cooling.

Applications

As in the case of many of the systems described previously, the main applications for preparative gel

electrophoresis systems are large biomolecules such as nucleic acids, enzymes and antigens. Recent developments in preparative gel electrophoresis, however, have extended its applicability to the preparation of enantiomerically pure pharmaceuticals (**Figure 5**). This has been achieved by the addition of a sulfated β -cyclodextrin chiral additive to the buffer of a system employing a vertical column agarose gel in the apparatus shown in **Figure 4**.

Future Developments

The continued development of analytical and preparative instruments can only lead to further improvements in some of the systems previously mentioned. Limitations in design and development of these devices are reducing significantly as engineering and electrical methodologies improve. In contrast to the continuing development, and more widespread use of preparative gel electrophoresis, continuous free-flow electrophoresis instruments offer an interesting prospect for development now that the problems of convection have been more fully addressed by the use of capillary cooling.

PREPARATIVE SUPERCRITICAL FLUID CHROMATOGRAPHY

Introduction

Supercritical fluid chromatography (SFC) on a preparative scale is of interest because of its advantages over high performance liquid chromatography (HPLC). The high diffusivity and low viscosity of supercritical fluids allow rapid separation. The solvent strength can easily be controlled by changing pressure and/or temperature, so that mobile phases with a fixed composition can be used to separate many types of solute. Furthermore, many supercritical fluids are volatile or gaseous under normal ambient conditions, so that solutes can easily be recovered from the collected fractions by depressurization.

Preparative-scale SFC is now being used to separate high-value materials where preparative HPLC can be difficult to use. Peaks are narrower in SFC and for these difficult separations, very little overloading can be done to take advantage of this. Consequently, the maximum amount of material obtained in a run is of the order of 100 mg in preparative SFC, compared with the much larger amounts which are sometimes obtainable in preparative HPLC. Large-scale SFC systems can either be built in the laboratory or purchased commercially.

The unique physicochemical properties of supercritical fluids have convinced many workers that preparative SFC might be useful and relatively simple compared with preparative gas chromatography (GC), which is unsuitable for involatile and thermolabile compounds, and preparative liquid chromatography (LC), in which fraction-eluent separation can be problematic.

Preparative SFC is based on the following steps: periodic injection of the feed into a continuous flow of eluent, chromatographic separation due to selective interactions of the components of the sample with both the eluent and the stationary phase, detection at the column outlet, fraction collection, separation of the fractionated compounds from the eluent, further purification of the compounds and, optionally, recycling the eluent (Figure 1).

Preparative-scale SFC can be divided into two types: small-scale and large-scale. Small-scale can be

defined as the isolation of milligrams to a gram of pure product for, say, structure analysis. Bench-scale equipment derived from common analytical apparatus can be used with the adoption of nondestructive detection, fraction collection and eluent removal. However, for industrial-scale production (1 g h^{-1} to 1 kg h^{-1}), large-scale equipment has to be used, posing different problems, even if the same concept is applied. In preparative SFC, most studies have been devoted to the former aspect.

History and Development

Preparative-scale SFC was first suggested in 1962 by Klesper *et al.* and an appropriate collection apparatus was constructed 10 years later by Jentoft and Gouw (Table 1). However, it was not until 1982, 20 years after it was first suggested, that a patent appeared on the technique from Perrut. Two years later, Chapelet-Letourneux and Perrut were the authors of a meeting abstract on preparative SFC. In 1986, the first papers were published by Ecknig and Polster, followed months later by an article from Jusforgues *et al.*

In the 1980s, predictably, reports of preparative SFC were small in number. However, during the 1990s, the total amount of material published on

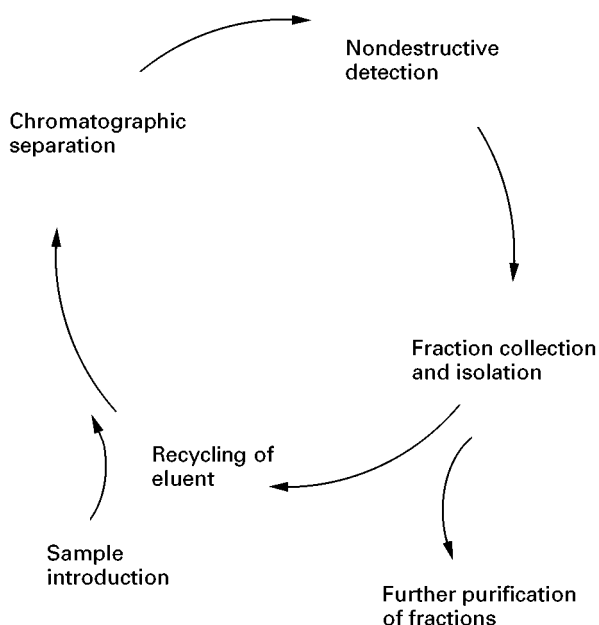

Figure 1 Flow diagram of the basic steps of preparative SFC.

Table 1 Historical perspective of preparative-scale supercritical fluid chromatography (SFC)

Year	Development
1962	SFC was suggested as a preparative tool
1972	Preparative SFC collection apparatus constructed
1982	First patent on preparative SFC published
1984	First meeting abstract on preparative SFC appeared
1986	First papers on industrial-scale preparative SFC published
1988	Jasco produce first commercial semipreparative SFE-SFC system
1990	First commercial process-scale SFC system by Prochrom

SFE, supercritical fluid extraction.

preparative-scale SFC has slowly increased; recently, publications have remained steady at three or four per year (Figure 2).

The early work was performed on SFC systems built in the laboratory. At the end of the 1980s, commercial equipment became available from Jasco and Prochrom.

During the development of preparative-scale SFC, it was used for the separation of relatively simple, low-cost test substances, such as paraffins. Once the technique had been refined, it was applied to high-value complex samples, such as pharmaceuticals.

Instrumentation

A general preparative-scale SFC consists of a pumping system, a core chromatographic section (an injection loop, a column and a detector) followed by the

back-pressure regulator (BPR) and fraction collection system. Depending on the type used, the collection system may be located either before or after the BPR (Figure 3). The discussion in this section will be limited to the example in Figure 3, with further examples being explored later.

Pumping System

The pumping system must be capable of delivering the mobile phase (e.g. carbon dioxide modified with methanol) at a total flow rate of above 30 mL min^{-1} and at a pressure of up to 400 bar. Such a system requires judicious choice of pump with an efficient cooling system to ensure that the carbon dioxide is pumped as a liquid. The carbon dioxide pump, the modifier pump and the mixer may be integrated into one pumping system or may be separate components (as in Figure 3). An accurate method of delivering modified carbon dioxide must be used for reproducible results. The use of a single and dual pumping system has been investigated. Many methods have been developed to allow the addition of a modifier to a premixed mobile phase. The former can deliver an accurate flow of modifier while the composition of a premixed mobile phase can vary with use. A flow-splitting method has been used where a fraction of the carbon dioxide displaces the modifier, after which the flows are recombined. The dual pumping systems allow one pump to control the carbon dioxide flow while the other controls modifier flow.

Syringe pumps have been used, but with the high flow rate required on larger preparative systems, their relatively small capacity limits their use. Thus, a reciprocating dual pumping system is becoming the

**Figure 2** Growth in the number of research papers published on preparative SFC. The numbers quoted do not include review articles, poster presentations or meeting abstracts. Open boxes, cumulative, filled boxes, annual.

most common because it is able to deliver a continuous stable flow.

Injection System

The injection system may be located inside the column oven to allow injection into a supercritical fluid or outside, as in Figure 3. The injection system most commonly used is as in HPLC, but much work is being applied to the development of novel injection methods for preparative SFC. It has been noted that large-volume injections, such as those required in preparative separations, may cause phase separations of the mobile phase and the injection solvent. Although not always so, this may have detrimental effects on the efficiency of separation. To overcome this, much work has been successfully focused on the development of a solventless injection system, where the injection solvent is removed prior to introduction to the column. The sample can then be focused on a pre-column, thus eliminating any band broadening.

Columns

The most common columns used in preparative SFC are standard HPLC columns. For small-scale preparative work, analytical columns can be used. However, for larger-scale separations, preparative columns are necessary. A wide range of packing is available; the most common type is octadecylsilane bonded phases.

Detection

Preparative SFC is compatible with the detection methods available in both GC and HPLC. The most common detector for preparative SFC is the ultraviolet-visible (UV/Vis) detector. Although more sensi-

tive, the flame ionization detector (FID) is not often used because of restrictor plugging, which occurs when the highly concentrated effluent is introduced. In addition, most organic modifiers cannot be used with the FID. However, less sensitive refractive index detectors or an evaporative light-scattering sensor can be used as a universal detector if necessary. To enhance and allow many separations in SFC, a polar modifier must be used as carbon dioxide alone does not have sufficient polarity. The use of a modifier thus reduces the number of detection methods available, unless specific modifiers are chosen, for example, an FID can still be used with carbon dioxide modifier with formic acid or formamide.

Back-pressure Regulators

The BPR is used to maintain SFC system pressure above the critical pressure of the mobile phase. The BPR can be a simple restrictor like a capillary tube of either fused silica or stainless steel having appropriate dimensions for the required back-pressure and flow rate. However, in order to change the back-pressure using the same piece of restrictor, one needs to change the flow rate because the back-pressure is only produced by flow resistance. Although fused silica restrictors are the most common and cheapest BPR, they can be blocked by certain solutes or samples during use, and they can break when some organic solvents are used, or if scratched.

Another type of back-pressure device is a mechanical or electrical feedback regulator. This is a complex regulator which consists of a pressure-sensing device and a needle valve. The regulator can control the back-pressure irrespective of the mass flow rate of the fluid. Although more expensive than a restrictor, it is much less likely to become blocked. The supercritical fluid depressurizes in the BPR and emerges at atmos-

pheric pressure as a gas (carbon dioxide) and as a liquid (modifier), and it is then that the separated material is deposited into or on a collector.

Collection Methods

Many trapping methods have been tested and developed in preparative SFC. The mobile-phase modifier can be used as a trapping fluid. This was demonstrated by Heaton and co-workers who fractionated polycarboxylic acid mixtures. They found that purities were close to 100%. In-line trapping methods have proved to be just as efficient. Many different collection methods have been investigated using pressurized pre-BPR and depressurized post-BPR traps. Comparison of four depressurized collection methods showed that a collection solvent and/or cooling of the collection vessels was required to achieve good recoveries. Without these measures, recoveries fell dramatically. Collection into pressurized vessels was compared with deposition on to semipreparative thin-layer chromatography (TLC) plates and the latter gave poorer recoveries.

Principles of Separation

The principles of preparative SFC can be illustrated by taking a mixture of two compounds present in equal proportions. Providing their peaks are well resolved, a graph of purity against the fraction of material collected in total will look like curve 1 in Figure 4. The first half recovered will be a pure fraction of one of the compounds. The second half, collected separately, will contain the other compound. This is the ideal situation. For a poorer separation, curve 2 is encountered. Here, the second compound begins to elute before all the first has been collected. In the worst case, illustrated by curve 3, both compounds elute together.

Figure 4 Plot of purity versus fraction collected for different degrees of separation.

Figure 5 Plot of purity versus production rate for different degrees of separation.

Optimization

The variables to be optimized include the type of column, the concentration of modifier (if any), pressure, temperature, flow rate and loading.

Usually, optimization of column type, pressure, temperature and modifier concentration is conducted on an analytical scale. Initially, the chromatograms from experiments without trapping are scrutinized to help choose the best conditions.

However, for the optimization of flow rate and loading conditions, trapping experiments can be performed to obtain plots of purity against production rate for different conditions. The rate of production of the eluent from the end of the column can be improved by increasing flow rate or loading, for a given set of conditions. However, this can have a deleterious effect on separation. Consequently, if purity is presented versus rate of production, the curves 1, 2 and 3 (Figure 4) will become extended (Figure 5). The horizontal dotted line in Figure 5 signified 95% purity and it dissects the curves 1, 2 and 3 at i, ii and iii, respectively. These points can also be shown as a graph of production rate against loading or flow rate for a purity of 95% (Figure 6). Consequently, it can be seen how an optimum loading or flow rate can be chosen for a given purity.

Figure 6 Plot of production rate versus loading or flow rate for a given required purity.

Figure 7 Chromatogram of the separation of a chiral benzimidazole.

For purities less than 100%, the purity versus production rate curves can be fitted to a quadratic. The resultant equations can be exploited to calculate values of production rate at a given purity for the various loadings. Plots can then be produced of production rate against loading. Consequently, an optimum loading can be obtained for a required purity.

Applications

The relatively low throughput of preparative SFC dictates that the technique is only economically viable for high-value substances, such as natural products, polymers and pharmaceuticals.

Probably the most promising area for preparative SFC is in chiral separations where several applications have been reported. The racemates of important biological compounds have been isolated into their optically pure forms. Shorter analysis times have also been observed when performing chiral separations of β -blockers, benzodiazepines, non-steroidal anti-inflammatory agents and β -agonists. An example of the separation of a chiral benzimidazole and 2,2,2-trifluoro-1-(9-anthryl)ethanol achieved using SFC is shown in Figures 7 and 8.

Preparative SFC has been applied successfully to polymers. Highly isotactic (*-it*) and highly syndiotactic (*-st*) fractions of poly(methyl methacrylates) (PMMA), where the degree of polymerization (DP) ranges from 25 to 50, have been isolated by Ute *et al.* (1993). This represents an improvement on earlier work where the same authors preparatively separated

PMMA with DP ranging from 19 to 29. An example of separation of a PMMA is shown in Figure 9.

Preparative-scale separations using supercritical fluids have been coupled to reaction systems to separate products of synthesis reaction. Jacobson *et al.* designed a supercritical fluid synthesis system with on-line preparative SFC using supercritical ammonia. ^{14}C -labelled anisole, L-methionine and 4-methoxyphenylguanidine were isolated and found to have a radiochemical purity of >98%.

Several compounds of pharmaceutical and biological interest have been isolated by preparative SFC and it has been reported that the supercritical technique was faster and more efficient than preparative HPLC.

Large-scale preparative SFC is a promising method for producing valuable fractions free from solvent and, at first glance, it is surprising that there have been so few reports on semi-industrial preparative SFC separations. In practice, however, problems have been reported with mobile-phase recycling, mobile-phase product separation, sample injection, fraction collection and columns, all of which are more crucial than on a smaller scale.

Conclusions

Preparative SFC is still applied to only a minority of compounds and is underutilized, although the number of applications for which it has been used is increasing. As SFC is used on a wider variety of compounds, many of these applications will undoubtedly be transferred to the preparative scale.

Figure 8 Chromatogram of the separation of 2,2,2-trifluoro-1-(9-anthryl)-ethanol.

Figure 9 Chromatogram of the separation of a poly(methyl methacrylate).

The main disadvantages associated with using HPLC as a preparative separation technique are not experienced with SFC, namely the removal of the collected sample from the mobile phase and subsequent disposal of the mobile phase.

PRESSURIZED FLUID EXTRACTION: NON-ENVIRONMENTAL APPLICATIONS

J. L. Ezzell, Dionex Corporation, Salt Lake City
Technical Center, Salt Lake City, UT, USA

Copyright © 2000 Academic Press

Introduction

Pressurized fluid extraction (PFE), also referred to as accelerated solvent extraction (ASE), is a liquid

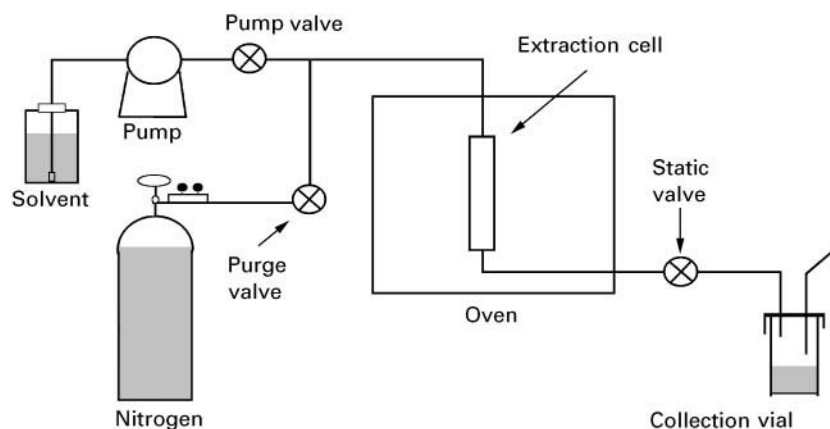

Figure 1 Schematic diagram of a pressurized fluid extraction (PFE) system.

solvent extraction technique developed and introduced by Dionex Corporation in 1995. While the initial applications focus of this technique was the environmental area, the versatility and ease of use of the approach has proven useful for laboratories performing extractions in the food and polymer industries, as well as in the pharmaceutical and consumer products areas.

Traditional reflux based extraction techniques such as Soxhlet extraction can take anywhere from 8 to 48 h to perform, with 24-h extractions common. Other liquid solvent based extraction techniques such as wrist shaker, hot-plate boiling and sonication require copious amounts of solvent and often involve labour-extensive steps such as filtering or concentration prior to extract analysis. One thing that they all have in common is operation at ambient pressure. An increase in temperature beyond the boiling point of the solvent is not possible owing to solvent evaporation.

Pressurized fluid extraction is performed by using the same solvents as in the traditional approaches, but at higher temperatures than is possible in these techniques. This increase in temperature improves the kinetics of the process, resulting in more efficient extractions (faster and using less solvent) compared with traditional approaches. The solvents are used under pressure so that their liquid state is maintained at the heated conditions. For example, solvents such as water, methanol, acetone or hexane are routinely used in PFE at 75–150°C. The solvents are maintained as liquids under pressure, normally at 10.4 MPa (1500 psi). PFE is therefore performed using very hot liquids to expedite the extraction process.

The flow-through design of the technique results in extracts which do not require the extended work of filtration as a means of separating the sample matrix

from the extracted analytes. In further contrast to traditional extraction approaches, all of the basic steps of PFE are amenable to automation, freeing the analyst from the labour-intensive nature of most sample preparation protocols. Automated PFE systems can extract up to 24 sample cells, and have the necessary safety considerations for unattended operation built in.

Instrumentation

A schematic diagram of a PFE system is shown in **Figure 1**. The PFE extraction procedure consists of a combination of dynamic and static flow of solvent through a heated extraction cell containing the sample. These cells must be capable of safely withstanding the pressure requirements of the system, and are normally constructed of stainless steel, with frits in the end caps to allow the passage of solvent while retaining the solid sample. Disposable cellulose or glass fibre filters may be used in the cell outlets to avoid compaction of fine particles on the frit surface, which may impede the solvent flow. Solvent pressure is regulated via a high-performance liquid chromatography (HPLC) type pump and outlet valves control the flow of solvent from the cell to the collection vial. Compressed nitrogen is used to purge all of the liquid from the cell into the vial at the completion of the extraction.

Sample Preparation

Proper sample preparation is essential in order to obtain efficient and reproducible extractions. The ideal sample for extraction is a dry, finely divided solid, in which the extraction solvent can easily and thoroughly penetrate the sample matrix. Whatever can be done, within reason, to make samples ap-

proach this definition will be beneficial to the extraction process. Generally, samples should be prepared for PFE extraction in the same manner as traditional techniques. Samples with large particle size (> 1 mm) should be ground so as to increase the surface contact of the matrix and solvent. Wet or sticky samples should be mixed with drying agents such as sodium sulfate or Hydromatrix (pelleted diatomaceous earth), or with dispersing agents such as Ottawa sand prior to extraction. Typical sample sizes used in PFE are 1–30 g of solid or semi-solid material.

Sample Extraction Parameters

Extraction Solvent

As extraction parameters, solvent choice and temperature will have the greatest impact on extraction efficiency with PFE. An extraction solvent should be chosen which will solubilize the target analyte(s), but leave the majority of the sample matrix intact. This is normally done by matching the polarity of the solvent and analyte. PFE extraction can be performed with the entire range of aqueous and organic solvents, with the exception of strong mineral acids (hydrochloric, nitric, sulfuric) which will attack the stainless steel flow-path of the system. In those cases where an acidic pH is required, small amounts (1–5%) of acetic, phosphoric or other weak acids can be used. The choice of solvent should also be considered in the light of the post-extraction analysis technique. Solvents such as methanol and acetonitrile are suitable for direct HPLC injection, while solvents such as hexane, methylene chloride or acetone are more suitable for concentration and gas chromatography (GC) analysis. If the target compounds are easily oxidized, solvents should be degassed prior to use. It has been observed that solvents which perform only marginally well at ambient temperature often perform quite well at elevated temperature. This increases the range of solvent choices available to the analyst considering PFE, as more than one solvent may give good recoveries of target analytes. The selection of the appropriate solvent can then be made based on selectivity of extraction, solvent cost, safety and exposure factors, and compatibility with post-extraction processing steps. Solvent mixtures should also be considered in cases where minor adjustments to polarity are desired.

Extraction Temperature

PFE extraction can be performed from ambient temperature to 200°C. Increased temperature will increase the efficiency of the extraction process, and this should be optimized short of the point at which

analyte degradation or excessive co-extraction of matrix components occurs. Many PFE applications are performed in the 75–150°C range, with 100°C as the recommended starting point for new methods development. In this temperature range, significant increases in extraction efficiency are observed without the breakdown of target compounds. If an extraction is to be performed on a compound with a known degradation point, then the PFE method should be developed to operate below that point. Extractions performed at low (40–70°C) or ambient temperatures may be sufficient for analytes which are weakly or only surface bound to the sample matrix. The extracts generated using PFE will be similar in composition to those produced by other techniques using the same solvents. If a post-extraction clean-up step is required following a Soxhlet extraction, the same process will most likely need to be performed following PFE.

Extraction Pressure

Although essential to the process, pressure is not generally considered a critical parameter in PFE. Normal operating pressures of 10.3–13.8 MPa (1500–2000 psi) are well above the threshold pressures required to maintain the solvents in their liquid states at PFE operating temperatures. The main purpose of using pressures in the ranges indicated is to provide rapid filling and flushing of the extraction cells. Typical PFE extractions are performed in 12–20 min, although this time can be extended for difficult samples. In addition, multiple static cycles can be used periodically to introduce aliquots of fresh solvent during the extraction process.

Method Development

When developing a method for PFE the following approach has proven useful. A representative sample should be prepared as outlined above; select an extraction cell size which most closely matches the desired sample size. The extraction cells do not need to be filled completely, but a full cell will use less solvent in the extraction process than a partly filled one. Select the extraction solvent using the considerations listed above, although normally the same solvent or solvent mixture used in a traditional liquid extraction method is used. Extract the sample starting with the standard PFE conditions: pressure = 0.3 MPa (1500 psi), temperature = 100°C, heat time = 5 min, static time = 5 min, flush volume = 60% of cell volume, purge time = 60 s, static cycles = 1.

Extract the same sample multiple times in order to assess the efficiency of the method. If there is significant analyte present in the second or third extracts,

adjust the following parameters (one at a time), and repeat the validation process:

1. Increase the temperature (use 20°C steps).
2. Add a second or third static cycle.
3. Increase the static time (use 5-min increments).

If these steps do not result in a complete extraction, re-examine the sample preparation steps and/or the choice of extraction solvent.

Applications: Food

PFE extraction in the food industry is used for both the analysis of natural components such as fat, and to detect the presence of contaminants such as residual pesticides. New labelling requirements require food manufacturers to describe more accurately the total fat content of their products. This requires adequate monitoring of both raw and processed food samples. Pesticide residue analysis in foods has been, and will continue to be, a persistent and necessary analytical challenge. Proper selection of extraction solvent with food matrices can limit the high level of co-extractables typical with these sample types.

Fat Extraction

The determination of total fat in powdered infant formula is performed using a solvent mixture of hexane–acetone (4:1) at 100 or 125°C. Three 5-min static cycles are used in the method. Milk-based formulas are prepared by mixing 1 g of sample with 3 g of hydromatrix prior to cell loading and extraction at 125°C. Soy-based and hydrolysed milk-based formulas are mixed with wet hydromatrix (3 g + 0.4 g water) and extracted at 100°C. PFE extraction of these samples can be performed without the aggressive alkaline pretreatments required by some methods. Extraction results were compared directly with results obtained using alkaline pretreatment followed by Majonnier extraction with a mixture of petroleum ether, diethyl ether and ethanol (AOAC Method 932.06). The results obtained for the PFE extracts averaged 99.7% of the Mojonnier results for six different formula types, including a certified reference material (SRM 1846) available from the National Institute of Standards and Testing (NIST). The fat content was determined gravimetrically, and verified by fatty acid methyl ester (FAME) analysis.

Fat extraction from a variety of meat samples is performed by mixing 3–4 g of a homogenous meat sample with 6 g of hydromatrix. Moisture can be removed from the samples by drying in a microwave oven prior to extraction. Up to five samples can be dried at once in an 800 W oven at full power for

Table 1 Pressurized fluid extraction (PFE) and Soxhlet results for the extraction of fat from a variety of high fat processed meat samples

Sample	% Fat by PFE	Standard deviation (n = 3)	% Fat by Soxhlet
Beef	40.74	1.12	40.85
Pepperoni	42.66	0.28	43.15
Chorizo	27.98	0.22	27.84
Bacon	46.66	0.82	46.83
Sausage	33.80	0.28	33.54

3 min. Samples are then extracted using either petroleum ether or hexane at 125°C, with two, 2-min static cycles. Extraction results were compared with a 4-hour soxhlet extraction with petroleum ether (AOAC Method 90.39). The results for a variety of samples are shown in Table 1. The PFE method used here was shown to be useful for both low and high fat meat samples and results in a considerable time savings compared with the traditional approach.

Pesticide Residues

Using methods originally designed for soil samples, pesticide residues can be efficiently extracted from food samples including raw grains and fruits and vegetables. Wet samples should be mixed with sodium sulfate or hydromatrix prior to extraction. Extraction of organochlorine pesticides is performed using a solvent mixture of 10% acetone in hexane at 100°C. This solvent mixture limits the amount of co-extractables which are present in extracts produced with higher percentage acetone mixtures. Organophosphorus pesticides can be recovered with acetonitrile, ethyl acetate, methanol or acetone/methylene chloride mixtures, at temperatures ranging from 60 to 100°C. The more polar pesticides and herbicides, such as the sulfonyl ureas, can be efficiently extracted with a mixture of acetone and 0.1 M ammonium carbonate aqueous solution (20:80) at ambient temperature.

Applications: Polymers

PFE extraction in the polymer area has focused on additive analysis and general product structure characterization. For quantitative extraction of polymer matrices, samples should be ground prior to analysis. This can be accomplished with a liquid nitrogen grinder (cryo-grinder) as opposed to conventional laboratory grinders. Another major consideration in PFE extraction of polymers is the choice of extraction solvent. In other application areas the solvents used in existing methods are generally transferred and used in the PFE method. Traditional polymer methods,

however, swell and/or dissolve the sample matrix by boiling in a nonpolar solvent, followed by cooling and precipitation of the polymer. In PFE extraction, the goal is to separate the target additives of components from the sample matrix. The use of nonpolar solvents in this application will simply dissolve the entire sample and move it to the collection vial, or worse, it will precipitate in the transfer lines and plug the system flow path. The strategy developed for PFE extraction of polymers is to select a relatively polar solvent, which will solubilize the target analytes while leaving the majority of the sample matrix intact. Temperature is used to soften the matrix and a small amount of nonpolar solvent is added to increase penetration of the matrix. Cellulose thimbles are often used inside the PFE extraction cells to facilitate loading of the ground sample (normally 0.5–1.0 g) and prevent softened polymer from sticking to the sides of the vessel. Since small amounts of polymer matrix may be present in the extracts, samples are normally passed through a syringe filter prior to HPLC or GC analysis.

Additives from Polypropylene and Polyethylene

UV stabilizers, antioxidants and antislip agents are routinely added to polymer formulations to modify their properties for specific applications. Extraction and analysis of these compounds is essential in order to monitor that formulation levels are within specification. The antioxidant products (Irganox®, Irgafos® (Ciba Inc.), Erucamide, etc.) are a group of compounds commonly used in both low and high density polyethylene (LDPE and HDPE, respectively) preparations. Extraction of these compounds is performed at 140°C, using a solvent mixture of 2.5% cyclohexane in isopropyl alcohol. Three, 3-min static cycles are used to produce optimum results. Using these conditions, values equivalent to the results from reflux based extraction methods can be obtained. Chimassorb®944 (Ciba Inc.) is extracted from polypropylene (PP) using acetonitrile at 150°C. PFE can also be used to monitor the loss of Irganox 1076 which occurs after γ -irradiation.

Plasticizers in PVC

Traditional extraction of plasticizer content from polyvinyl chloride (PVC) is performed according to ASTM D 2124 recommendations. This method uses 120 mL petroleum ether in a 6-h Soxhlet extraction. The PFE method developed for this application uses petroleum ether at 100°C, with three, 1-min static cycles. The method does not require post-extraction filtering. GC analysis of the compounds extracted – dioctyl adipate (DOA), trioctyl phosphate (TOP),

Table 2 Extraction of plasticizers from polyvinyl chloride (PVC) by pressurized fluid extraction (PFE) and Soxhlet

Compound	PFE %	Soxhlet %
DOA	9.81	9.56
TOP	9.50	9.28
DOP	9.42	9.35
TOTM	9.17	9.05

dioctyl phthalate (DOP) and trioctyl mellitate (TOTM) – showed average recovery of 101.7% relative to the reflux method (Table 2).

Total Extractables from Styrene-butadiene Rubber

Styrene-butadiene rubber (SBR) is used in the manufacturing process of many consumer products including automobile tyres. The total extractable content of the rubber consists of oils and organic acids, and is usually measured gravimetrically. The PFE method developed for this application uses 2-propanol at 150°C, with three, 3-min static cycles. The results shown in Table 3 indicate an average recovery of 99.9% relative to the target value.

Structure Characterization

The extraction of monomers and oligomers from formed polymers is used as an indicator to assess the completeness of the polymerization reaction. The extraction of monomer (caprolactam) from nylon-6 and oligomers (dimer, trimer) from 1,4-butylene terephthalate (PBT) was performed at 170°C with hexane-ethanol (60:40). Results indicate that recoveries equivalent to Soxhlet were obtained.

Applications: Pharmaceuticals

PFE extraction is used in the pharmaceutical industry both in the quality control of finished products and in the characterization of raw materials and product candidates. Extractions are normally performed on 1–10 g samples at temperatures ranging from ambient to 100°C, using polar solvents such as water,

Table 3 Total extractables from styrenebutadiene rubber (SBR) by pressurized fluid extraction (PFE)

Sample	PFE %	Standard deviation (n = 3)	% Recovery
1	32.66	0.17	100.2
2	32.77	0.04	100.5
3	33.89	0.19	100.1
4	34.44	0.31	98.9

methanol, ethanol and acetonitrile. Tablets, plants and other samples of large size should be ground prior to extraction.

Natural Products

The extraction of capsaicinoids from cayenne fruit, Hypericin from St John's Wort and alkaloids from goldenseal root is performed using ethanol, methanol or acetonitrile as extraction solvents at 100°C. St John's Wort extracts were analysed by UV/VIS absorbance at 516 nm following alumina cartridge clean-up to remove co-extracted chlorophylls. Hypericin content (measured as total dianthrone) was determined to be 0.44% with a %RSD = 4.1 ($n = 4$). This was consistent with a label claim of a minimum 0.3% hypericin. Goldenseal root was extracted according to the same conditions and analysed for total berberine content. HPLC analysis showed a total berberine content of 1.44% with a %RSD of 2.8 ($n = 4$). Water was also investigated as a potential solvent but was shown to extract too much of the samples matrix, which complicated the final analysis. In other studies, PFE extraction was compared with Soxhlet, reflux and steam distillation techniques for the extraction of St John's Wort, horse chestnut seed, milk thistle fruit, tumeric rhizome and thyme herb. Using methanol and temperatures ranging from 50 to 100°C, results comparable to or better than those obtained following USP method guidelines were obtained.

Animal Feeds

Extraction of an animal feed containing spiked levels of an anti-schizophrenic drug being tested in rats was performed at 100°C with methanol. Cattle feed containing the veterinary medicinal lasalocid (coccidiostat) was extracted using methanol containing 0.3% acetic acid at 80°C. Both extracts were analysed by HPLC and produced results comparable (96–105%) to the existing wrist-shaker techniques.

Transdermal Patches

Extraction of finished product is an essential part of the pharmaceutical quality control process. Transdermal patches containing nitroglycerin were extracted using ethanol at ambient temperature. The backing was peeled off of the patch and the sticky side was pressed onto sand in order to prevent the patch from sticking to itself. The patch, either 10 or 20 cm², was then curled into the extraction cell and Ottawa sand added as inert filler. The results shown in Table 4 indicate a recovery of the active compound at 96–99% of the result obtained from the standard method, which involved extended shaking and extract filtering prior to analysis.

Table 4 Recovery of nitroglycerin from transdermal patches using pressurized fluid extraction (PFE) and wrist shaker methods

Sample	PFE (mg)	SD ($n = 10$)	Wrist shaker (mg)	SD ($n = 10$)
10 cm ² patch	31.4	0.44	31.7	0.48
20 cm ² patch	62.0	2.4	64.6	0.71

Ocular Inserts

Extraction of diclofenac sodium (anti-inflammatory) from an ocular insert used following cataract surgery was performed using methanol at 100°C. The polymeric tube containing the drug was cut into pieces prior to loading into the extraction cell. Results showed a recovery of 99.1% with a %RSD of 2.5 ($n = 8$). The PFE method replaces a 16-h Soxhlet extraction requiring 200 mL of solvent per sample.

Tablets

Extraction of felodipine (anti-hypertensive) in tablets was performed using acetonitrile at 100°C. Quantitative recovery (98%) from a single tablet was obtained by wrapping the tablet in a filter paper and crushing it. The crushed tablet and filter paper were then added to the extraction cell. Extraction of whole, uncrushed tablets resulted in less than adequate recovery.

Applications: Consumer Products

Tobacco

PFE extraction of tobacco is currently used to assess the total content of nicotine and other active and marker compounds, as well as flavour characterization and carbohydrate and sugar analysis. The extraction of raw and processed tobacco is performed with a variety of polarity solvents and at temperatures ranging from 50 to 100°C, depending on the types of compounds being targeted.

Detergents

Extraction of the organic constituents of granular and liquid detergents is performed using ethanol at 150°C. The conventional reflux extraction method used to determine total alcohol extractables is a multi-step process requiring 700 mL of solvent and 4 h to complete. The PFE extraction method for this sample is complete in 12–18 min and uses 15 mL of solvent per sample. Liquid detergent samples are mixed with an equal weight of hydromatrix prior to loading into the extraction cell. The results summarized in Table 5 show an average recovery of

Table 5 Recovery of organic extractables from granular and liquid detergents using pressurized fluid extraction (PFE) and reflux extraction methods

Sample	PFE %	Reflux %
Granular 1	22.40	22.16
Granular 2	33.49	34.10
Granular 3	39.22	38.50
Granular 4	22.76	21.80
Granular 5	30.69	30.10
Liquid 1	45.35	44.35
Liquid 2	55.87	55.25

101.6% obtained with PFE compared with the conventional method, with a threefold improvement in reproducibility.

Textiles

The total extractable content of sized warp yarns is typically performed using AATCC Method 97-1995. This method is a series of three extractions using water, enzyme (bacterial amylase) and trichloroethane (TCE). Cotton and cotton/polyester yarns are extracted using PFE with water at 180°C, followed by extraction with TCE at 50°C (no enzyme was used). This method yields results slightly greater than those obtained with the standard method for total extractables by gravimetric determination and iodine spot test for polyvinyl alcohol and starch removal.

Paper

Total extractables from paper pulp is performed using methylene chloride at 125–150°C. Samples are prepared by cutting or shearing into small strips prior to cell loading. Three, 3-min static cycles are used to generate results of 101% of the standard reflux extraction method (analysis performed gravimetrically).

Summary

Conventional extraction times range from 4 to 48 h whereas PFE extractions are normally performed in 12–20 min. While the decrease in extraction time is favourable for most laboratories in general, it can be critical for those industries where laboratory data is used in feedback control of production cycles and manufacturing quality control. The volume of solvents used in PFE can be as much as 10–20 times less

than traditional extraction methods. When factors such as safety and analyst exposure, as well as solvent purchase and disposal costs are considered, the benefits of PFE can be quite substantial for most laboratories. When compared directly with traditional extraction techniques, the recoveries generated by PFE normally equal or slightly exceed the comparative method. The ability of PFE to use the same liquid solvents used in traditional methods allows for rapid conversion to this technique, without much effort involved in methods development. Once a PFE method has been developed for a class of compounds, that same method can be successfully applied to a variety of matrix types without adjustment to extraction parameters. This lack of matrix dependency has allowed a very small set of standard methods to be applied to a large number of sample types.

Introduction

Metabolism of free (nonesterified) arachidonic acid (5,8,11,14-*cis*-eicosatetraenoic acid) via the cyclooxygenase (COX) pathway produces a cascade of biologically active compounds collectively known as prostaglandins (PGs). These include prostaglandin D₂ (PGD₂), prostaglandin E₂ (PGE₂), prostaglandin F₂ (PGF₂), prostacyclin (PGI₂) and thromboxane A₂ (TXA₂) (Figure 1). The analysis of PGs and related compounds in isolated cells and organs has proved relatively easy. By contrast, measurement of PGs in plasma presents a more challenging analytical task. This is because: (1) a more complex mixture of chemically related compounds exists in plasma; (2) PGs exert their effects locally, i.e. within a short distance of their site of production, and are consequently rapidly metabolized; and (3) *ex vivo* generation of PGs may occur. PG metabolites are generally present in biological fluids, including plasma and urine, in higher concentrations than their precursors. These metabolites are not formed during processing and therefore the problem of generating artefactual results does not arise. It has been suggested that the measurement of PG metabolites in urine may represent a more reliable approach for assessing *in vivo* generation of PGs than does quantification of primary products in plasma.

Recently, it has been shown that free-radical peroxidation of polyunsaturated fatty acids (PUFAs) by a mechanism independent of the COX-pathway also produces novel families of PGF-like compounds. In contrast to the COX-derived products, COX-independent products are present mainly esterified to phospholipids and with the side chains across the cyclopentane ring in the *cis* orientation. Figure 2 illustrates the structural differences between COX-dependent and COX-independent 9 α ,11 α -PGF_{2 α} . COX-independently derived PGF-like compounds are collectively known as isoprostanes. The measurement of isoprostanes has received considerable attention because they have proved to be a reliable marker of oxidative stress. Determination of the different families of isoprostanes also allows the assessment of the peroxidation of individual PUFAs. Accumulating data indicate that the metabolic fate of

non-COX-derived PGF-like compounds is similar to that of the COX-derived products.

PGs and related compounds can be assessed by several methods including bioassay, radioimmunoassay (RIA), high performance liquid chromatography (HPLC) linked to RIA or UV or mass spectrometric (MS) detection and gas chromatography-mass spectrometry (GC-MS). GC-MS is the preferred method for the quantification and structural validation of PGs, combining the high resolution of GC separation employing fused silica capillary columns with the specificity and sensitivity of mass spectrometry.

Analysis of PGs by GC-MS

The analytical procedures for the isolation and determination of PGs in plasma and urine involve a number of steps.

Selection of an Internal Standard

The use of an internal standard is vital for accurate and precise assay of PGs and related compounds by GC-MS. An ideal internal standard should have similar physicochemical properties to the compound being analysed, and should be taken through the entire analytical procedure, i.e. extraction, enrichment and derivatization. Stable isotope-labelled internal standards are generally used for the assay of PGs and related compounds. These are prepared by replacing sufficient atoms of ¹H or ¹⁶O by the corresponding stable isotopes ²H and ¹⁸O. Many tetradeuterated [²H₄] PGs are commercially available. By contrast, carboxylic ¹⁸O-labelled PGs have to be synthesized. The following precautions should be considered during sample processing: (1) the amount of the internal standard should be at least of the same order as that expected for the compound being analysed; (2) the possibility of back-exchange of ²H by ¹H from water during alkaline hydrolysis or following catalytic hydrogenation should be considered; and similarly (3) back-exchange of carboxylic ¹⁸O by ¹⁶O in an esterase-rich environment such as plasma.

Isolation from Biological Samples

The strategies for the routine isolation of PGs and related compounds from biological samples involve

Figure 1 The release of arachidonic acid by phospholipase A₂ and its metabolism by the cyclooxygenase enzymes.

conventional solvent extraction and/or chromatographic separation involving solid-phase extraction (SPE) and thin-layer chromatography (TLC). In both situations, the samples are acidified to pH 2 to minimize ionization of the carboxylic groups of PGs. The solvent of choice for partitioning of PGs and related

compounds from biological samples is ethyl acetate. SPE entails passing the sample through a disposable octadecylsilica (C₁₈) cartridge. Lipophilic compounds are retained on the column while salts and polar compounds are removed by washing the column with water or water/acetonitrile. PGs are eluted from the

Figure 2 Structural differences between (A) COX-dependent 9 α ,11 α -PGF_{2 α} and (B) COX-independent 9 α ,11 α -(8-*epi*)-PGF_{2 α} .

column using a combination of organic solvents such as hexane, ethyl acetate and isopropanol. The final step in the purification of PGs and related compounds involves thin-layer chromatography (TLC); one-step TLC for plasma and two-step for urine. Replacement of the C₁₈ and TLC procedures with an aminopropyl-silica cartridge substantially increases the recovery of PGF-like compounds and reduces analysis time. Immunoaffinity chromatography has also been used for the purification of PGs from biological fluids. The advantages of this method over multistep procedures are: (1) its simplicity and shorter analysis times; (2) the addition of a further degree of specificity to the analysis. Unfortunately, its implementation has been limited to leading laboratories in the field because the column materials are not commercially available.

Exploiting a unique chemical property of a prostaglandin such as 2,3-dinor-6-oxo-PGF_{1 α} is another approach for the isolation of structurally related products (Figure 3). 2,3-dinor-6-oxo-PGF_{1 α} can exist in different isomeric forms depending on pH. At acid pH, the 2,3-dinor-6-oxo-PGF_{1 α} is converted to a lactone. This property allows isolation of 2,3-dinor-6-oxo-PGF_{1 α} from other polar compounds such as free fatty acids. Quantitative recovery of 2,3-dinor-6-oxo-PGF_{1 α} is achieved by hydrolysis in a mild aqueous base.

Plasma isoprostanes are mainly present esterified to phospholipids and therefore have to be hydrolysed prior to SPE and/or TLC processing. Briefly, plasma (1 mL) is incubated with 1 mol L⁻¹ aqueous potassium hydroxide at 45°C for 1 h to release esterified isoprostanes. The pH is then adjusted to 2 using HCl. The internal standard is added and the isoprostanes isolated as described above. For the analysis

of isoprostanes in tissue samples, homogenates (50–100 mg tissue mL⁻¹) are hydrolysed with 1 mol L⁻¹ potassium hydroxide at 45°C for 1 h. The pH is then adjusted to 2 and total lipids extracted with 10 volumes of ethyl acetate. Isoprostanes are then isolated by a single chromatography step on an aminopropyl cartridge.

Derivatization

Chemically untreated PGs are not suitable for GC analysis. Therefore, protection of functional moieties in PGs is carried out first to increase their volatility, improve chromatographic separation and to enhance assay sensitivity and specificity. The most common derivatization reactions used for PGs are: (1) esterifi-

Figure 3 Equilibrium between the ketone and lactone forms of 2,3-dinor-6-oxo-PGF_{1 α} .

cation of the carboxylic moieties; (2) etherification of hydroxy moieties; (3) methoximation of keto moieties; and (4) boronation of hydroxy moieties.

For the purposes of PG quantification by gas chromatography/negative ion chemical ionization (GC-MS/NICI), pentafluorobenzyl (PFB) ester derivatives of the monocarboxylic forms of PG are prepared. The reaction is carried out by incubating the final lipid extract in the presence of the catalyst *N,N*-diisopropylethylamine (DIPEA) at 45°C for 1 h. Methyl ester derivatives of PGs are prepared using diazomethane in ether solution. Methyl esters can also be prepared using methanolic solutions of hydrogen chloride or hydrochloric acid.

Hydroxy moieties are converted to trimethylsilyl (TMS) ether derivatives. Bis(trimethylsilyl)trifluoroacetamide (BSTFA) is the most frequently used derivatization agent. A quantitative conversion to trimethylsilyl ether is achieved by incubating standards or the final lipid extract at 60°C for 1 h or overnight at 4°C in the presence of DIPEA. *t*-butyl(dimethylsilyl) (BDMS) ether derivatives are occasionally prepared as an alternative to TMS because they produce fragments of higher relative molecular mass during mass spectrometric analysis. The main disadvantages of the BDMS derivatives are: (1) bulkiness that results in incomplete derivatization of stearic-hindered hydroxy moieties; and (2) relatively long retention times.

Hydroxy groups may also be converted to alkylboronate derivatives. Alkylboronate derivatives are prepared by incubating PGs and related compounds with *n*-butylboronic acid under anhydrous conditions. These derivatives are mainly employed to determine the stereochemistry of the hydroxy moieties in the prostaglandin F (PGF)-series. Alkylboronate derivatives can only be formed if both hydroxy groups on the cyclopentane ring of a PGF molecule are *cis* orientated.

Keto moieties of PGs and related compounds are converted to *O*-alkyloximes by incubating authentic standard or buffered urine with a saturated methoxyamine hydrochloride solution in pyridine. It is important to remove the derivatization reagent completely because it causes deterioration of the chromatographic column. Chromatography on a short column of Sephadex LH-20 is therefore advisable.

Hence, derivatization is carried out in the order: methoximation, esterification, boronation and finally silylation to minimize side reactions.

Injector

The most common techniques for introducing high boiling point compounds such as PGs into the GC are programmed-temperature vaporization (PTV) and

splitless injection. The PTV is designed to allow rapid heating and cooling of the injector. Briefly, sample (2 μ L in iso-octane) is introduced into a temperature-controlled injector that is initially maintained at 75°C and is then raised to 85°C immediately after injection. Since iso-octane has a boiling point of 98–99°C the temperature will be sufficient to evaporate the majority of the solvent and simultaneously concentrate the sample onto the surface of the injector, which is lined with inert glass. After allowing sufficient time for removal of excess solvent, the injector temperature is rapidly raised to 275°C. This ensures that volatilization of high boiling point components occurs and permits a quantitative refocusing of the analyte at the head of the column.

The alternative method for introducing PGs into the GC, i.e. using a splitless injector, relies on cold trapping and/or a solvent effect to refocus the analyte on the head of the capillary column. Sample (2 μ L in hexane) is usually introduced over a period of 30–60 s onto the column.

Column Heating

GC is performed using an oven temperature program that starts at an initial temperature of 80–100°C. The rates at which oven temperatures are increased range from 20°C min⁻¹ to 30°C min⁻¹. The final temperature will be 280°C or higher, depending upon the upper limit specified for the column being employed. The time over which the column is maintained at maximum temperature (e.g. 280°C) depends upon the elution time of the compound being analysed.

Detectors

Mass spectrometry is used to detect PGs as they emerge from a GC. This approach has proved to be a flexible, sensitive and selective technique. The most popular modes of ionization employed by prostanoid researchers are described below.

Electron impact (EI) The electrons used for the ionization have an average energy of 70 eV. Initial ionization energies for most organic molecules are between 8 and 15 eV. When a molecule enters the ionization chamber the high energy causes fragmentation of the parent compound. This mode of ionization provides information on the relative molecular mass and molecular structure of the compound. Methyl ester derivatives are mainly used for GC-MS/EI. Quantitative analysis is performed by selected ion monitoring (SIM) of fragments characteristic of the compound being analysed. The concentration of a particular component in the sample is calculated by determining the ratio of intensity of a certain ion in

Figure 4 Formation of a carboxylated anion corresponding to the intact molecule [M-PFB]⁻ or [M-181]⁻ during final analysis of PFB-esters by NICI.

the sample to that of the internal standard. The detection limit for GC-MS/EI is 200 pg injected onto the column.

Positive ion chemical ionization (PICI) PICI is a softer ionization technique than EI and therefore molecules are less likely to undergo fragmentation. This leads to an abundance of protonated molecular ions. The detection limit for GC-MS/PICI is a few nanograms.

Negative ion chemical ionization (NICI) PGs and related compounds are not good electron-capturing substances. However, they contain at least one terminal carboxylic moiety that can be esterified with electron-capturing groups such as pentafluorobenzyl (PFB) esters. As illustrated in **Figure 4**, the PFB ester forms a molecular ion after initial electron capture. This leads to the loss of the PFB radical and the formation of a stabilized carboxylated anion corresponding to the intact molecule [M-PFB]⁻ or [M-181]⁻. For most PFB esters, the carboxylate anion constitutes > 60% of the total ion. This makes NICI a highly efficient ionization process. The combined sensitivity and selectivity of NICI has made it the method of choice for quantitative analysis of PGs. Quantitative analysis is performed using selected ion monitoring (SIM) of the carboxylate anion [M-181]⁻. The detection limit for SIM is from 200 fg to 5 pg.

Gas chromatographic separation The most widely used stationary phase for fused silica capillary columns for the separation of PGs and related compounds is 100% dimethylsilicone commercially known as DB1, Rtx-1, SE-30, Sil-5 CB or Ultra 1. This phase has a CP-value of 5, CP-being an index that predicts selectivity and polarity for a given stationary phase. CP-values range between zero for a nonpolar stationary phase and 100 for the most polar. Other investigators have used an intermediate polarity stationary phase (CP = 19), typical commercial names being DB-1701, Rtx-1701 and Sil-19 CB. These stationary phases consist of a mixture of 86% dimethylsilicone, 7% phenylsilicone and 7% cyanopropylsilicone.

There have been problems with regard to the separation of 9 α ,11 α -PGF_{2 α} , 9 α ,11 β -PGF_{2 α} and 9 β ,11 α -PGF_{2 α} using both low- and medium polar stationary phases. Clear separation of all three PGF-ring isomers is of interest with regard to clinical conditions linked to increased production of 9 β ,11 α -PGF_{2 α} such as asthma and anaphylaxis. We have found that SPB-1701 (80% dimethylsilicone, 5% phenylsilicone, 15% cyanopropylsilicone), which is considered a medium polar stationary phase with a CP-value of 20, is superior to DB-1701 for the separation of PGF₂ isomers. The improved separation of the PGF₂ isomers using the SP-1701 may be explained by the dipole moment introduced by the cyanopropyl functionality. **Figure 5** shows a baseline separation of PGF₂ isomers including 9 β ,11 α -PGF_{2 α} , 9 α ,11 α -(8-*epi*)-PGF_{2 α} , 9 α ,11 β -PGF_{2 α} and 9 α ,11 α -PGF_{2 α} . The signal monitored at *m/z* 569 represents the carboxylated anion of the PGF₂ isomers as PFB ester/TMS ether whereas that at *m/z* 573 represents the tetradeuterated 9 α ,11 α -PGF_{2 α} internal standard.

Figure 6 shows a typical example of a SIM chromatogram obtained with simultaneous monitoring of 6-oxo-PGF_{1 α} , 2,3-dino-6-oxo-PGF_{1 α} , TXB₂, 2,3-dinor-TXB₂ and 11-dehydro-TXB₂ in human urine using a DB1 column. PGs and related compounds were purified by immunoaffinity chromatography and the final lipid extract was sequentially converted to PFB ester, methyloxime and TMS ether derivatives prior to analysis by GC-MS/NICI.

Figure 7 shows a baseline separation of *syn* and *anti* isomers of urinary PGD metabolites as PFB ester/methyloxime/TMS ether derivatives using a DB-1701 column. The peaks labelled I and II (*m/z* 514) represent the *syn* and *anti* isomers of urinary PGD metabolite. The signal monitored at *m/z* 522 is the tetraoxygen-¹⁸O-labelled PGD metabolite internal standard. The peaks labelled III and IV represent a COX-independent urinary PGD-metabolite. As can be seen, *syn* and *anti* isomers derived from PGD are fully resolved by capillary gas chromatography.

There is less agreement on the best GC conditions for the separation of C₂₀-isoprostanes. C₂₀-isoprostanes are a series of PGF₂-like compounds derived from peroxidation of arachidonic acid by a mechanism independent of the COX pathway. Peroxidation

Figure 5 Gas chromatographic separation of the PGF₂-isomer as PFB ester/TMS ether derivatives using an SP-1701 column (30 m; 0.25 i.d.; film thickness 0.25 μ m). (A) PGF₂-isomers; (B) tetradeuterated PGF_{2 α} as the internal standard. (Reproduced from Nourooz-Zadeh *et al.*, 1995, with permission from Elsevier Science.)

of arachidonic acid at positions C₇, C₁₀ and C₁₃ would produce four families of PGF₂-like compounds. Each sub-family would have 16 diastereoisomers, since the hydroxy groups on the prostanoic skeleton can be arranged in the 2³ configuration. Theoretically, 64 C₂₀-isoprostane isomers can be formed during the peroxidation of arachidonic acid. Of these, 9 α ,11 α -(8-epi)-PGF_{2 α} , has received considerable attention because it is commercially available and has been shown to be biologically active. Both DB1 and DB1701 stationary phases have been used to assay C₂₀-iso-

prostanes in biological samples. A comparison of typical GC-MS/NICI chromatograms for 9 α ,11 α -(8-epi)-PGF_{2 α} in human plasma using DB-1701 and SP-1701 is shown in Figure 8. Once again, the SP-1701 phase is superior to the DB-1701 phase in separating the *R* and *S* isomers of 9 α ,11 α -(8-epi)-PGF_{2 α} . To the best of our knowledge, no chromatograms have been published for the analysis of C₂₀-isoprostanes as PFB esters/BDMS in human plasma.

The SP-1701 stationary phase is also useful for the separation of C₂₀- and C₂₂-isoprostanes (PGF₃ and

Figure 6 Selected ion monitoring chromatograms of simultaneous analysis of urinary 6-oxo-PGF_{1α}, 2,3-dinor-6-oxo-PGF_{1α}, TXB₂, 2,3-dinor TXB₂ and 11-dehydro-TXB₂ using a DB1 column (30 m; 0.25 i.d.; film thickness 0.25 μm). (Reproduced with permission from Barrow *et al.* (1989) *Biochimica Biophysica Acta* 993: 121-127.)

PGF₄-like compounds, respectively) in biological samples. The order of elution for the isoprostanes is C₂₀-PGF₂ followed by C₂₀-PGF₃ followed by C₂₂-PGF₄, with clear separation between the different species. Therefore, this unique property of the SP-1701 phase facilitates the parallel determination of all three classes of PGF-like compounds in a single sample. A typical GC-MS/NICI chromatogram for the separation of PGF₂- and PGF₄-like compounds in human brain tissue is shown in **Figure 9**. The upper spectrum monitored at *m/z* 569 represents C₂₀-PGF₂-like compounds. The middle at *m/z* 593 represents

C₂₂-PGF₄-like compounds, while the lower spectrum at *m/z* 573 is the internal standard.

Identification of Compounds Based on their Retention Times

Reproducibility of chromatographic separation is important for the identification of a given compound in biological samples. For routine purposes, identification of a particular component is based on its retention time relative to that of an isotope-labelled internal standard. During GC separation on capillary columns, ²H-labelled internal standard elutes 1–2 s earlier than the corresponding unlabelled compound. Carboxylic ¹⁸O-labelled internal standard appears at the same retention time as the corresponding unlabelled PGs or their metabolites. Co-injection of a mixture of the samples of interest with an appropriate amount of external standard also adds a degree of confidence to the identification of the compounds based on their relative retention times.

Preparation of a Standard Curve for Quantification

A calibration curve for a given compound is prepared by plotting the peak height ratio of the unlabelled prostanoid/labelled analogue against the concentration of the compound being analysed. Such plots are generated using least-squares linear regression analysis and provide a gradient and intercept for the determination of the concentration of the corresponding unlabelled component in the sample.

Inter- and Intra-Assay Coefficients of Variation

These are determined by adding a known amount of an external standard to a sample that contains the compound of interest at a low concentration. At least four samples are required to provide an intra-assay coefficient of variation (COV). To establish the inter-assay COV, a minimum of four samples should be prepared on at least four occasions with different calibration curves.

Conclusions

The use of multistep chromatographic procedures in combination with GC separation on a medium polar capillary column and electron capture detection is the best approach for the analysis of PG and related compounds in biological samples. The method can be used for a wide range of lipid peroxidation products formed by mechanisms dependent or independent of the COX pathway. This is particularly important in

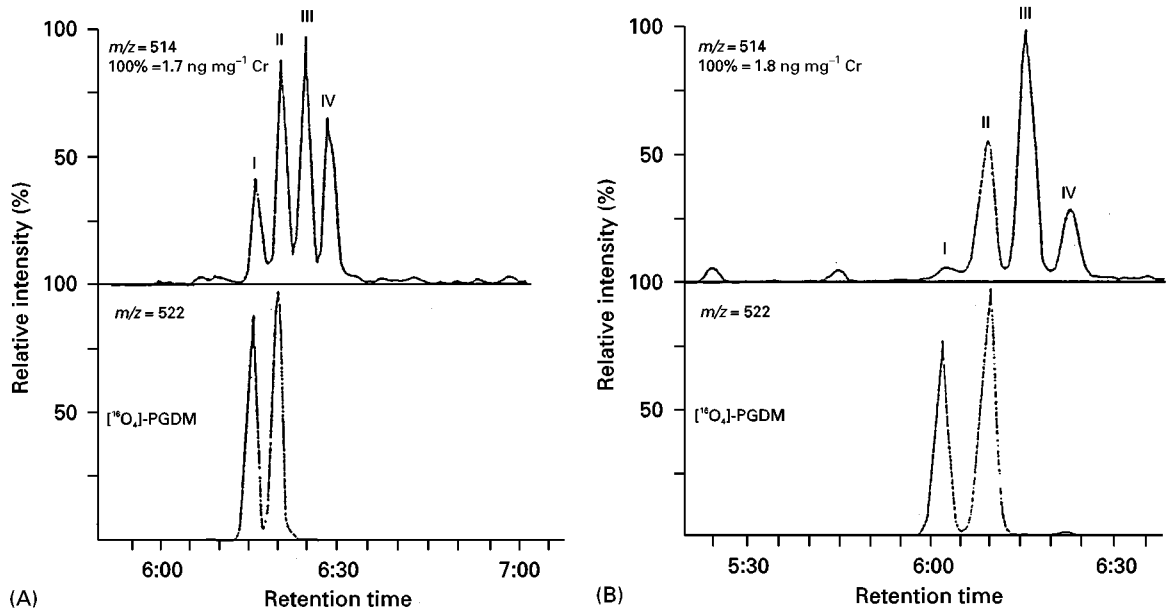

Figure 7 Selected ion monitoring chromatograms of analysis of urinary PGD metabolites using a DB1701 column (15 m; 0.25 inner diameter; film thickness 0.25 μ m). (Reproduced with permission from Morrow JD *et al.* (1991) *Analytical Biochemistry* 193: 142–148).

the measurement of urinary isoprostanes and their precursors because nonenzymatic peroxidation of individual PUFAs produces an array of PGF-like com-

pounds. The sensitivity and specificity of the assay can be improved by using GC-MS/MS or GC-tandem MS.

PROTEINS

Capillary Electrophoresis

S. P. Radko, National Institutes of Health, Bethesda, MD, USA

Copyright © 2000 Academic Press

Electrophoresis, mostly in the slab gel format, and high performance liquid chromatography (HPLC) are the two techniques commonly employed for protein separation during the past decades. After emerging in the early 1980s, capillary electrophoresis (CE) has been recognized as a new tool for protein analysis and characterization: it combines a number of aspects of both electrophoresis and HPLC. Based on differences in charge-to-size ratio or isoelectric point (pI) of protein macroions, the separations in CE are inherently electrophoretic. However, online detection producing quantitative information in the form of peak area or height, single sample analysis in a serial fashion, and the possibility of performing separation in the presence of flow (generated by electroosmotic current) are features of CE similar to those of HPLC. These features lend CE to easy automation, in contrast to the labour-intensive methods of conventional (gel) electrophoresis. Since heat dissipation by convection is effectively suppressed in capillaries of less than 0.2 mm i.d., the separation can be performed in free solutions without a gel. The high heat dissipation properties of thin fused silica capillaries also enable one to apply field strengths of several hundred volts per centimetre, thus greatly reducing the time of separation.

To date, CE techniques analogous to a number of conventional electrophoretic methods such as zone electrophoresis, isoelectric focusing and sieving (size-dependent) separations have been developed and numerous applications of CE to separation and characterization of proteins have been demonstrated. In the particular mode of CE as capillary zone electrophoresis, short separation times (often a few minutes) combined with relatively large diffusion constants of proteins were expected to provide separation efficiencies exceeding a million theoretical plates. However, such potential efficiency has never been practically achieved, and this mostly appears to be due to the interactions of proteins with the capillary walls.

The approaches to reducing protein interactions with the capillary walls and the modes of CE applied to protein analysis are briefly considered below.

Approaches to Reducing Protein–Silica Surface Interactions

The high surface activity of fused silica at neutral pH, combined with the high surface-to-volume ratio of thin capillaries is a major problem in applying CE to protein separation. In general, the protein–silica surface interactions give rise to peak broadening and asymmetry, compromising the resolution. In bare fused silica capillaries, these interactions often result in uncontrolled alterations of the electroosmotic flow (EOF) and irreproducible migration times, low mass recovery of proteins or even their irreversible adsorption with loss of sample. Over the last 10 years, great efforts have been made to develop conditions for protein analysis under which the protein–capillary wall interactions are minimized and the EOF is either suppressed or stabilized.

In the pH range of 3–10, the charge density of the capillary inner surface is known to increase progressively due to the ionization of weakly acidic silanol groups. The charge density on the wall is near zero at pH < 3 (silanol groups become fully protonated) and saturated above pH 10 (silanol groups are fully dissociated). Thus, protein species possessing a pI higher than the pH of the electrophoretic buffer will experience an electrostatic attraction to the negatively charged silanols. Beside silanol groups, fused silica bears a variety of other active sites such as inert siloxane bridges and hydrogen-bonding sites. These active sites can join in the protein immobilization on the inner surface of the capillary, by interacting with the hydrogen-bonding and hydrophobic regions of the protein.

The electrostatic attraction between protein molecules with a net positive charge at a given pH and ionized silica is believed to play a key role in the protein–capillary wall interactions. Thus, operating at extremes of pH (at pH < 3 where silanol ionization is very low or at pH > 11 where proteins carry a net negative charge) appears to be the simplest approach to their minimization. Though such an approach has been demonstrated to be successful in a number of applications, operation at pH extremes in general reduces charge diversity, diminishing the separation selectivity. The pH extremes also tend to

denature proteins and induce formation of multiple conformers. The electrostatic attraction between proteins and the silica surface may be reduced by increasing the ionic strength of electrolyte solutions (100 mmol L⁻¹ or greater). However, the high ionic strength limits the applied voltage, consequently decreasing efficiency and increasing the analysis time. Deactivation of silanol groups may also be achieved by derivatizing them with organosilanes but the carbon moieties of organosilanes make the capillary wall highly hydrophobic.

Two approaches appear to be the most successful in rendering CE suitable for routine protein separations: first, incorporation of appropriate additives into the electrolyte solution to mask or compete for either the silanol groups or the basic amino acid residues of the protein which are exposed to the solution; and second, use of capillaries with an inner surface modified by an adsorbed or covalently attached polymeric coating. A large variety of chemicals and modification procedures currently exist which can effectively reduce protein-wall interactions and control the EOF so that a separation efficiency of several hundred thousands of theoretical plates has become practically achievable. Several types of coated capillaries are commercially available, and are described below.

The incorporation of buffer additives permitting successful protein separations in bare fused silica capillaries has the advantage of simplicity. Ideally, the buffer additive should not compromise the selectivity of separation by interacting with the analyte, alter the buffer pH or increase the operating current, and should in general exhibit low UV absorbance. Organic compounds of different kinds have been extensively examined as the buffer additives. Since mostly they interact with the silica surface in a dynamic fashion, the method of modifying the capillary walls by using buffer additives is known as dynamic coating.

A large database of organic compounds and buffer components suitable for improving CE performance in protein separations has been established. This database includes zwitterionic salts (methylglycine and trimethylglycine, trimethylammoniumpropyl and butyl sulfonates), an extensive number of mono-, di- and polyamines, surfactants (ionic and zwitterionic fluorosurfactants as well as nonionic surfactants of the Brij and Tween series) and neutral polymers (cellulose derivatives, dextran, polyvinyl alcohol, polyethylene glycol). However, the effectiveness of dynamic coatings is mostly evaluated with standard mixtures containing a small number of proteins or with variants of a single protein. Therefore, it is not possible to predict how a particular additive

will act in conjunction with complex biological samples. Such samples may consist of a broad spectrum of proteins ranging widely in their degree of hydrophobicity, pI values and molecular weight. Despite this limitation, the present database of buffer additives known to improve protein separations may be very useful in developing methods for a targeted component analysis like the purity control of recombinant proteins, food analysis, or electrophoretic analysis of haemoglobins, serum or urine proteins.

Though the main mechanism by which the buffer additives improve protein separation appears to be their interaction with the silica surface, they can play an additional role – binding to the protein. In a number of cases, the additives have been shown to modulate selectivity by enhancing differences in electrophoretic mobility (e.g. some surfactants upon complexation to proteins, or alkyl diamines and their derivatives upon binding to protein glycoforms).

The incorporation of diaminealkanes, polyamines and fluorinated cationic and zwitterionic surfactants in the electrophoretic buffer effectively controls both the magnitude and direction of EOF.

Adsorbed coating differs from dynamic coating by the degree of permanence, but the demarcation line between them is arbitrary. In the case of an adsorbed coating, the coating agent should not be present in the electrophoretic buffer during a run. As a rule, polymeric species are used for adsorbed coating. Permanence can result from the high binding affinity of the coating agent to the silica surface (polymeric amines, polyethylene oxide) and may be enhanced by subsequently cross-linking the adsorbed species into a continuous, permanent film (e.g. polyethyleneimines treated with diepoxide after adsorption to capillary walls). The permanence can also result from the ability of the coating agent to form, upon a particular treatment, polymeric films physically covering the silica surface (cellulose acetate and polyvinyl alcohol films are examples). The polymers may be adsorbed not directly to the silica surface but to a hydrophobic layer formed by moieties of a surfactant covalently attached to the capillary inner walls (hybrid coating). Hybrid coating appears to be the most flexible, since the polymeric layer can easily be removed by rinsing the capillary with an organic solvent and polymeric species of other types may be adsorbed, depending on the separation goal. An example of protein separation in a capillary with the hybrid coating is presented in **Figure 1**.

The covalently attached polymeric coating is usually carried out by grafting polymers to a silica surface derivatized with organosilanes. In the subsequent step, polymer chains may be cross-linked to help stabilize the coating. Several neutral (cellulose

Copyright: Wiley-VCM.

derivatives, epoxy polymers, dextran) and cationic (polyvinylimidazole, polyethyleneimine derivatives) polymers have been employed for the covalently attached coating. The most popular polymer used for the polymeric coating is polyacrylamide. This coating is mostly performed with polyacrylamide chains polymerized *in situ*.

It should be noted that, despite the variety of materials and procedures used to prepare the coated capillaries, they do not appear to vary markedly in separation properties. The diversity of chemistries underlying the capillary coating is likely to reflect the continuous search for a 'magic' coating and inadequacy of any single approach to provide satisfactory results for all applications. A particular problem arises due to difficulties in optimizing the coating process. The quality of coating appears to depend on the quality of the fused silica surface, which may vary between different sources of capillaries and even between different batches of silica; this requires a corresponding adjustment in capillary pretreatment and coupling chemistries.

Modes of Capillary Electrophoresis Applied to Protein Analysis

Capillary zone electrophoresis (CZE), capillary isoelectric focusing and sieving capillary electrophoresis

in polymeric media are the modes of CE most widely used for separating and characterizing proteins. A number of commercial kits for capillary isoelectric focusing and sieving separations are now available. Capillary isotachopheresis has in rare cases been employed for protein analysis. Micellar electrokinetic chromatography has generally exhibited a poor selectivity in separating proteins. This is probably due to the inability of relatively large protein molecules to partition into the detergent micelle.

Capillary Zone Electrophoresis

CZE is the simplest of the CE modes and straightforward to perform (Figure 1 depicts a typical example of a CZE separation). When employing CZE for protein separation, the choice of capillary (uncoated or with the particular type of coating) and buffer additives should be made carefully depending on sample composition. The uncoated capillaries generally require a prior conditioning step. Detection based on either UV adsorption or laser-induced fluorescence (LIF) is most often employed in the CZE of proteins. Depending on the detection mode, a sample pretreatment may be necessary.

The sensitivity of the detection by UV absorbance is limited since both the optical length (= capillary internal diameter) and sample volumes (typically, a few nanolitres) are very small in CZE. Though the sensitivity can be greatly increased by detecting proteins in the wavelength range of 200–220 nm, UV detection still requires a relatively high concentration of analyte in a sample. That is not always the case and a preconcentration of the sample, often of a volume of a few microlitres, is needed. Several online and offline preconcentration techniques can be employed in CZE. The first and simplest approach to online sample preconcentration is zone sharpening by stacking. Proteins dissolved in a buffer with a conductivity lower than that of the run buffer (commonly, the diluted run buffer) become concentrated at the interface between the sample and the run buffer due to a high voltage drop in the sample zone. Preliminary sample desalting is often necessary for this approach and special methods have been developed for desalting (and concentrating) microlitre volumes of protein samples, using small pore polyacrylamide gels.

Isotachopheresis is the other popular technique to concentrate samples. The preconcentration may be performed either online or in a coupled column, and in the presence of salts. The gain in detection limit is 10- to 100-fold and can be increased up to 1000-fold when a hydrodynamic counterflow is employed. Another efficient method of protein preconcentration is selective accumulation of the proteins on

a solid-phase affinity support. This method has been used in both online and offline modes, with several hundred-fold concentration.

After derivatization with a fluorophore, proteins may be detected online by LIF. A number of fluorescent dyes capable of covalently binding to protein molecules (e.g. fluorescein, naphthalenedicarboxaldehyde and fluorescamine) have been used, providing mass detection limits in the attomole range (initial sample concentrations of 10^{-8} to 10^{-10} mol L $^{-1}$). However, covalent binding of the dyes frequently results in a broadening of protein peaks or even in the formation of multiple peaks due to multiple derivatization.

Capillary Isoelectric Focusing

Like conventional isoelectric focusing (IEF), capillary isoelectric focusing (cIEF) is based on differences in isoelectric points (pIs) of proteins. In cIEF, a stabilizing gel is not required and, due to the high field strength, the focusing process usually takes only 5–15 min. The cIEF can provide resolution of up to 0.01 pH units, comparable with that of the most successful applications of conventional IEF.

Sensitivity of detection based on UV absorbance (at 280 nm) is generally satisfactory for cIEF, due to the concentration of proteins from a relatively large injected volume into a small volume of the focused zone. Capillaries with a hydrolytically stable coating effectively preventing protein adsorption and changes in the EOF are required for successful cIEF separations. As in conventional IEF, protein precipitation due to the high protein concentration at the isoelectric point is a potential problem in cIEF and is addressed in the same way: using strong solubilizing agents, such as urea and nonionic detergents, in the ampholyte mixture.

Size-dependent Separation of Proteins by Capillary Electrophoresis

Although the use of narrow bore capillaries abolishes the need for gel media to suppress convection, another important feature of gels – their capability to provide size-dependent separation of macromolecules – is clearly beneficial for protein analysis. Efforts to adopt gels to the capillary format were made in the early days of CE. However, technical difficulties, such as bubble formation and the fast deterioration of polyacrylamide gels during serial runs, limit the use of gel-filled capillaries. These difficulties have been overcome by using replaceable sieving media such as solutions of entangled polymers. While gels are polymerized *in situ*, polymer solutions are usually prepared by dissolving commercially available polymers in the run buffer and are pumped into the capillary before each run. Solutions of dextran,

polyethylene oxide, polyvinyl alcohol and linear polyacrylamide have been demonstrated to be suitable for protein analysis. Though the use of coated capillaries is generally recommended, uncoated capillaries may also be employed if a polymer solution produces sufficient viscosity (typically >100 cP). The main drawback of polymer solutions is that resolution is not as high as that obtained with gel-filled capillaries.

Size-dependent separation by CE of protein–sodium dodecyl sulfate (SDS) complexes provides information similar to that obtained from conventional SDS-polyacrylamide gel electrophoresis (SDS-PAGE), as illustrated in **Figure 2**. The limits of UV detection are comparable to those obtained in SDS-PAGE with Coomassie blue staining, whereas total analysis time for multiple samples is even shorter for CE than that for, e.g. a 16-channel slab gel. Size-based analysis by CE in sieving media under native conditions has been demonstrated for proteins. Usually, such analysis employs constructing a Ferguson plot (the logarithm of protein mobility vs. polymer (gel) concentration). Such construction is extremely time-consuming in traditional PAGE but becomes practical by using CE in replaceable sieving media. The Ferguson plot-based analysis may also be useful in estimating the molecular weight of proteins whose binding with SDS is anomalous (e.g. membrane proteins, glycoproteins, highly basic proteins) and that of aggregates and complexes of proteins.

Protein Characterization by Capillary Electrophoresis

In addition to the targeted component analysis and sample profiling, CE has been employed in a number of specific electrophoresis-based approaches aiming at the characterization of protein–ligand interactions, protein functional activity and structure.

Affinity capillary electrophoresis (ACE) has been applied to the study of protein interactions with drugs, carbohydrates, nucleic acids and other proteins. In a typical ACE experiment, the receptor is subjected to electrophoresis in a capillary containing free ligand at different concentrations. The receptor–ligand binding (K_{on}) and dissociation (K_{off}) constants are estimated by Scatchard analysis of shifts in the receptor's mobility in response to ligand concentrations. The analysis of peak broadening has been shown to be useful for estimating K_{on} and K_{off} constants, if the characteristic times of receptor–ligand interactions are comparable with migration time of the analyte. The receptor–ligand complex equilibrium and separation process can be affected by capillary wall effects and/or the use of buffer additives. These limitations must be addressed when developing an ACE method.

The potential of CE in analysing antibody–antigen complexes has been extensively studied over the last few years in order to develop CE-based immunoassays (IA). The CE-based IA offers advantages of high speed of a single analysis, detection of antigen at trace concentrations (10^{-10} mol L⁻¹ if the LIF detection and fluorescently derivatized antibodies are employed) and the potential for automation. Despite some successful examples, CE has generally exhibited the inability to perform direct IA due to the lack of separation between bound and free antibodies. Though this drawback has been overcome in the competitive CE-based IA, the sensitivity of the competitive IA does not meet the detection levels required for many important clinical tests.

A CZE-based approach to microassaying enzyme activity has recently been developed. In this 'in-tube' approach, the enzyme and substrate are electrophoretically mixed inside the capillary under conditions where their mobilities differ. Another new application of CZE to protein characterization is studying protein folding/unfolding transitions. Due to recent advances in capillary coating and the inherent ability to perform electrophoresis in short time intervals, CZE appears capable of reliably distinguishing different forms of protein conformations, providing a new instrumental approach to the quantitative analysis of the conformational equilibrium of proteins.

Coupling Capillary Electrophoresis to Other Techniques for Protein Analysis

Several multidimensional separation systems for protein analysis, incorporating CE, have been proposed over the last decade. Two-dimensional (2-D) techniques such as CE-CE (using CE separations with two different carrier systems), HPLC-CZE, size exclusion chromatography (SEC)-CZE, and even a 3-D technique combining SEC-HPLC-CZE have been reported. The multidimensional systems possess tremendous resolving power and may be extremely useful in analysing complex biological samples, but there are drawbacks. Separation times are generally long and can last 2–12 h. Beside the technical difficulties of interfacing different separation systems, the compatibility of mobile-phase and run buffers as well as maintaining the detection sensitivity adequate for trace analysis in the sequential separations are the most significant problems.

By coupling CE with mass spectrometry (MS), the molecular weight of separated proteins can easily be determined. It is also possible, using MS, to detect proteolysis and deamidation, find glycosylation variants, and, with peptide mapping, confirm the primary structure of proteins. Though online interfacing of CE with MS has progressed substantially in recent years, the successful online combination of CE and MS is still a challenging instrumental problem. In addition to the interface design issue, practical considerations concerning the compatibility between the run buffer and the sheath liquid as well as differences in their flow rates at the interface must be addressed when dealing with CE-MS coupling.

Conclusions

After an initial period of fast technical progress, over the last decade CE has been increasingly focused on developing practical methods for protein separation and characterization. To date, due to advances in capillary coating, CE may be viewed as a practical tool for rapid, sensitive and quantitative analysis of minute amounts of protein samples, with great utility in targeted component analysis. For many applications, it can replace HPLC and conventional gel electrophoresis but more often it should be used in conjunction with other separation techniques, providing different selectivity or automated analysis. Since the acceptance of CE in the clinical laboratory for routine protein-based diagnostics depends considerably on meeting adequate throughput, attempts to develop high throughput CE systems are likely to be intensified. With a decrease in the real cost and improvement in sensitivity and resolving power of

MS detection, the increasing use of a combined CE-MS technique can be expected.

To be more widely accepted in the area of biomedical research, CE-based protein separations must demonstrate a number of features that match the success of conventional (gel) electrophoretic systems. Besides profiling complex protein samples, these systems allow for immunological and enzymatic assaying of separated proteins as well as for simultaneous transfer of sample components into another separation dimension without altering the separation in the first one. All of these are achieved with minimal disturbance of zone integrity. Thus, the major efforts will probably be made in developing both multidimensional separation systems involving CE and CE-based separation systems permitting post- or on-column enzymatic and immunological analysis of the separated components of complex biological samples. Incorporating immobilized enzymes or antibodies into CE-MS systems will revolutionize the analysis of protein structure and, especially, glycoprotein analysis.

Introduction

Modern technological developments have made centrifugation one of the most important and widely applied techniques in experimental research. In biological studies centrifugation is used for the extraction and isolation of biological materials and for the measurement of physical properties of macromolecules. Indeed, biological materials have been extracted and isolated for more than a thousand years using centrifugal forces. In the 1920s, Svedberg and other researchers developed motor-driven centrifuges which had an optical system to observe sedimentation of macromolecules during centrifugation, and used these instruments for the measurement of physical properties of macromolecules, especially proteins. The molecular mass of most proteins was determined using these analytical centrifuges until 1970, but they

have not been recently used for that purpose because much easier methods for the measurement of molecular mass, such as size exclusion chromatography and sodium dodecyl sulfate (SDS)-gel electrophoresis, have been developed. More recently, centrifugation has become an indispensable tool for the isolation of proteins, nucleic acids and subcellular particles. The use of centrifuges has also been revived for the measurement of physical properties of proteins, especially for the characterization of protein associations and protein-protein interactions. In this section, important points of theory and practice for the separation and isolation of proteins by centrifugation are summarized.

Theoretical Basis of Centrifugation

Although a rigorous understanding of sedimentation theory is not required for the separation and isolation of proteins, a review of some basic principles will be helpful for understanding the establishment of conditions and the interpretation of experimental results obtained. Because of their random thermal motion,

macromolecular particles in a solution do not show any perceptible sedimentation in a uniform gravitational field. However, these macromolecular particles do sediment under a centrifugal force. If the effect of diffusion is neglected, in a solution (density ρ) the motion of a particle (mass m and volume V_p) that is located a distance r from the axis revolving with angular velocity ω can be expressed by the following equation:

$$vf = m\omega^2 r - \rho\omega^2 r V_p \quad [1]$$

where v is the velocity of the sedimenting particle, f its frictional coefficient; $m\omega^2 r$ the centrifugal force and $\rho\omega^2 r V_p$ the buoyant force. This equation may be rearranged to give:

$$v = dr/dt = s\omega^2 r \quad [2]$$

where:

$$s = \frac{m - \rho V_p}{f}$$

This is the well-known sedimentation equation in which s is the sedimenting coefficient and has dimensions of time. For most biological macromolecules, the magnitude of s is about 10^{-13} s. Therefore, the unit of sedimentation, the Svedberg (S), has been defined as being equal to 10^{-13} s. The standard sedimentation coefficient ($S_{20,w}$) is defined as that equivalent to sedimentation in water at 20°C. The sedimentation coefficients ($S_{20,w}$) of some proteins are shown in Table 1.

The sedimentation coefficient s may be transformed to a more practical form. The mass of 1 mole of particles, M , is

$$M = mN_o \quad [3]$$

where N_o is Avogadro's number. Thus, a particle's volume, V_p , may be expressed in terms of its molar mass:

$$V_p = mv = vM/N_o \quad [4]$$

where v is the particle's partial specific volume.

Eqns [1], [3] and [4] may be combined to give:

$$vf = \frac{M(1 - v\rho)\omega^2 r}{N_o} \quad [5]$$

When eqns [2] and [5] are combined, s may be expressed as:

$$s = \frac{v}{\omega^2 r} = \frac{M(1 - v\rho)}{N_o f} \quad [6]$$

Since the particle's partial volume, v , may be expressed by the reciprocal of the buoyant density of the particles, ρ_p , as $v = 1/\rho_p$, s may also be expressed as:

$$s = \frac{v}{\omega^2 r} = \frac{M(1 - \rho/\rho_p)}{N_o f} \quad [7]$$

Since $f = 6\pi\eta r_p$, where η is the viscosity of the liquid medium and r_p is the radius of unsolvated spherical particle, these equations indicate that the sedimentation velocity, v , is related to the sedimentation coefficient s , which is mostly a function of particle size, density of the particle ρ_p , density of the medium ρ and the viscosity of the liquid medium, η . In other words, for a given particle, sedimentation is directly related to particle size, particle density and the centrifugal field, and inversely to the viscosity and density of the liquid medium.

Centrifugation for Protein Separation

Centrifuges may be classified on the basis of the maximum speed, namely, low speed, high speed and ultracentrifuges. Each of these can be used in the various steps of protein separation and isolation from biological materials. Low speed centrifuges are used routinely for the initial processing of biological samples. This type of centrifuge can be mainly used to isolate cells and organelles that contain target proteins by pelleting these materials. High speed centrifuges, with maximum speeds of 8000–25 000 rpm, are mainly used for the preparation of subcellular fractions. These centrifuges can generate about 60 000 g, which is enough to separate proteins from debris of cells and organelles. In order to isolate proteins from other proteins, ultracentrifuges are

Table 1 Sedimentation coefficients of some proteins

Protein	$S_{20,w}$
Cytochrome C (bovine heart)	1.71
Egg-white lysozyme	1.9
Insulin	1.95

Myoglobin (horse heart)	2.04
α -Chymotrypsin (bovine pancreases)	2.40
Pepsin	2.8
g-Actin	3.7
Lactate dehydrogenase (pig heart)	6.93
Catalase (horse liver)	11.2
Glutamate dehydrogenase (bovine liver)	26.6
Fibrinogen (human)	7.63
Haemocyanine (octopus)	58.7
Haemocyanine (snail)	100

required. Modern ultracentrifuges can generate approaching 1 000 000 g, which is sufficient to pellet even small proteins. Ultracentrifuges can be divided into two types: analytical and preparative. Analytical ultracentrifuges have a device by which the sedimentation rate of molecules can be optically measured during centrifugation and can be used to obtain data on the sedimentation properties of particles. The masses of most proteins were determined by these ultracentrifuges before development of simpler molecular mass determination methods. Eqn [4] indicates that the particle's mass $m = M/N_0$ can be determined from its sedimentation coefficient s , if its frictional coefficient f , is known, as indicated in eqn [6].

Preparative ultracentrifuges are designed for sample preparation. This kind of ultracentrifuge is also commonly used for quantitative estimations of sedimentation coefficients of particles in a density gradient, although the data obtained are not as accurate as those obtained using analytical ultracentrifuges. Preparative ultracentrifugation can be divided into two methods, namely differential ultracentrifugation and density gradient centrifugation. Differential centrifugation is based on the differences in the sedimentation rates of particles in samples. If a suspension of particles is centrifuged in a tube without a density gradient, each particle will move toward the bottom of a tube. In this case, the rate of sedimentation, v , is dependent upon s (eqn [2]). Since s is mostly a function of particle size, the rate of sedimentation is proportional to particle size. In the course of the ultracentrifugation, two fractions can be obtained from a solution of particles: a pellet containing sedimented particles and a supernatant solution of the unsedimented fraction. A given particle in the solution may sediment to the pellet or near the bottom, as illustrated in Figure 1. As might be expected, this centrifugation will first sediment the largest particles in the sample solution to the bottom of the tube. The only particle that is in purified form is the most slowly sedimenting one, but the yield is very low. The major problem with differential centrifugation is that the centrifugal force necessary to pellet the larger particles is also often sufficient to pellet the smaller particles initially near the bottom of the tube (Figure 1). To separate one particle from another effectively, a 10-fold difference in mass is usually required. Thus, this centrifugation is recommended for the separation of proteins from large particles such as cells or organelles. However, it cannot be used for the isolation of one protein from another because the partial specific volume, v_p , of most proteins (in eqn [6]) is not sufficiently different.

Eqn [6] assumes that centrifugation is performed in a homogeneous medium. However, centrifugation

Figure 1 Fractionation of particles by differential centrifugation. Reproduced with permission from Griffith (1979).

can be carried out in a solution of an inert substance in which the concentration increases from the top to the bottom of the centrifuge tube, i.e. density increases from top to bottom. In such density gradient centrifugation of a mixture of particles with different sizes or buoyant densities, a particle will become stationary when $(1 - v\rho)$ in eqn [6] is zero. Thus, various components will separate according to size or buoyant densities, and form bands or zones of particles with similar densities. Thus, the use of such density gradients greatly enhances the resolving power.

There are two types of density gradient ultracentrifugation: isopycnic and rate-zonal ultracentrifugation. In isopycnic centrifugation, separation is based on the centrifugation of particles in a density gradient through which the particles move until their densities are the same as those of the surrounding medium, i.e. in eqn [7], $\rho_p = \rho$ (Figure 2). The sample is mixed with a relatively concentrated solution of a low molecular mass substance, such as CsCl, and is centrifuged until the solution achieves equilibrium under the high centrifugal field. The low molecular mass substance forms a steep density gradient. It is not obligatory to load the sample on top of the gradient. In the centrifugation, particle size only affects the rate at which particles reach their isopycnic position. Since variations in amino acid composition give proteins with only slightly different densities, isopycnic centrifugation can be used only when proteins are associated with nonprotein components such as lipids or polysaccharides, and their density differences are sufficient for the separation. Various gradient media can be used for the separation of these proteins because proteins form a band at low density in most gradient media. For example, in addition to CsCl,

Figure 2 Types of density gradient centrifugation. (A) Rate-zonal centrifugation. (B) Isopycnic centrifugation using a preformed density gradient. (C) Isopycnic centrifugation using a self-forming gradient. Reproduced with permission from Rickwood (1992) by permission of Oxford University Press.

RbCl, NaBr or KBr can also be used to form shallower gradients for better resolution of these proteins.

Rate-zonal centrifugation is ideal for particles of defined size such as protein and RNA. In the rate-zonal ultracentrifugation, a mixture containing particles is layered on top of a density gradient. Loading the concentrated samples to the top of the gradient increases the eventual resolution of recovered particles. Sucrose is commonly used to form a density gradient. During centrifugation, particles move through the gradient at their characteristic sedimentation rates, forming zones that can be recovered at the end of the run (Figure 2). Because the

sedimentation rate is more affected by molecular size, the rate-zonal ultracentrifugation separates similarly shaped macromolecules largely on the basis of their molecular masses. It should be noted that particles separated by the rate-zonal centrifugation may not be homogeneous because particles with similar mass, even proteins, are sometimes heterogeneous.

Practical Aspects for Protein Separation by Centrifugation

Since rate-zonal centrifugation is commonly used for the separation of proteins, the following discussion will focus on a practical approach for this technique.

Types of Rotor

Preparative centrifuge rotors can be classified into four types: fixed angle, swinging-bucket, vertical and zonal. In fixed-angle rotors, the tubes are positioned at a fixed angle. These rotors are often used for differential ultracentrifugation and are very efficient for the separation of proteins from cells and organelles. Typically, a sample is loaded atop a gradient which reorients as the rotor is spun (Figure 3). During centrifugation, the larger particles are first sedimented across the tube, hit the wall of the tube, and slide down to form a pellet at the bottom.

Figure 3 Operation of fixed-angle rotors. (A) The gradient is prepared, the sample is loaded and the centrifuge tubes are placed into the rotor. (B) Both sample and gradient reorient during acceleration. (C) Bands form as particles sediment. (D) Bands and gradient are both reoriented when the rotor is at rest. Reproduced with permission from Rickwood (1992) by permission of Oxford University Press.

Efficiency for the pelleting of particles is high due to the short sedimentation path. However, fixed-angle rotors are not common for protein separation because the pelleting process also disrupts sample zones as particles sediment through the gradient. Thus, fixed-angle rotors are mainly used for the pelleting of materials.

For the separation of proteins from other proteins, especially for small scale separation, the swinging-bucket rotor is widely used for rate-zonal centrifugation. This type of rotor is also used for the estimation of sedimentation coefficients of proteins. As shown in **Figure 4**, in the swinging-bucket rotor, the sample tubes are loaded into individual buckets which hang vertically while the rotor is at rest. When the rotor begins to rotate, the buckets swing out perpendicular to the axis of rotation. In these rotors, resolution of particles is high because particles sediment with a relatively long path length. For the same reason, run times are generally longer. Many types of swinging-bucket rotors are commercially available. The centrifuge tube should be as long as possible if high resolution is the objective. For large volume samples, swinging-bucket rotors with wider tubes should be used because the sample can be loaded in a narrow zone while still reducing particle interactions during sedimentation.

Vertical rotors are suitable for isopycnic as well as for rate-zonal separations. However, this type of rotor is not practical for the separation of proteins. As a result of diffusion and reorientation during

centrifugation, sample bands will be significantly broader than analogous bands in swinging-bucket rotors. In addition, if the sample contains pellets or floats, these materials will distribute along the length of the tube and can subsequently contaminate the supernatant during reorientation at the end of run.

Choice of Density Gradient

A density gradient is essential for rate-zonal centrifugation to support the zones of particles as they sediment. In addition, the sample can be loaded on to the top of the gradient as a narrow zone and the increasing density from the top to the bottom of the density gradient suppresses mechanical disturbances. Moreover, the presence of a gradient of increasing viscosity serves to sharpen the sample zones during centrifugation. The density gradient material for protein separation requires the following properties.

1. The materials should be sufficiently soluble in water to produce the range of densities needed.
2. Solutions of the gradient materials should be adjustable to a pH and ionic strength that are not harmful to proteins in the sample.
3. The materials should not interfere with methods of analysis of the target protein.

Sucrose has most often been used as a gradient material. Sucrose is inexpensive and extremely soluble in aqueous media and can be used to produce density gradients ranging up to 1.35 g mL^{-1} . Thus, it is suitable for separation of almost all proteins in cells. Although concentrated solutions of sucrose have high osmotic potential that cause shrinkage of certain cells and organelles, the high osmotic pressure has relatively less effect on the biological properties of proteins. Generally, sucrose is relatively inert to proteins, although contaminants in many commercial sources of sucrose may interact with proteins. Such impurities can be removed by treatment with activated charcoal. However, it is best to purchase specially purified sucrose for density gradient work. To sterilize sucrose solutions, autoclaving (100°C or above) of the solution should be avoided and treatment with 0.1% diethylpyrocarbonate is recommended. As described above, isopycnic centrifugation can be used for the separation of different types of proteins. However, it should be noted that the density of sucrose, even of a saturated solution, is too low for the separation. For this purpose, RbCl , NaBr or KBr can be used to form shallower gradients for better resolution.

Glycerol is used to stabilize some proteins, especially membrane-bound proteins, and provides gradient densities ranging up to 1.26 g mL^{-1} . Thus, glycerol gradients are widely used for the separation

Figure 4 Operation of swinging-bucket rotors. (A) The gradient is performed and the sample is loaded on the top of the gradient. (B) Centrifuge bucket reorients as rotor accelerates to lie perpendicular to the axis of rotation. (C) Bands form as the particle sediment. (D) Rotor decelerates. Centrifuge bucket comes to rest in its original vertical position. Reproduced with permission from Rickwood (1992) by permission of Oxford University Press.

of proteins by rate-zonal separations. However, it should be noted that the high viscosity of glycerol reduces the effective density range and glycerol appears to inhibit some enzyme activities.

Preparation of Gradients

Density gradients can be divided into two types: continuous and discontinuous. For protein separation, continuous gradients are usually used in rate-zonal centrifugation. The most common continuous gradient for protein separation is a linear gradient in swinging-bucket tubes. A linear gradient is a gradient in which the density increases linearly in a tube of constant cross-sectional area with increasing distance from the centre of rotation. Thus, in this configuration the linear gradient can be defined as one where the density increases linearly with volume.

When designing a linear gradient in swinging-bucket rotors, several points should be emphasized. The density at the top of the gradient must be sufficient to support the sample while the density of the bottom of the gradient must not exceed the density of proteins to be separated. In general, the greater the slope of the gradient, the better the resolution obtained because the viscous drag rises rapidly as the sucrose concentration increases. Usually, as a first attempt, a 5–30% or 10–40% sucrose gradient should be used. It should be emphasized that the sample volume is related to the slope of the gradient because a given slope of gradient can only tolerate a limited amount of sample before gradient inversion occurs. Poor resolution during rate-zonal centrifugation almost always results from overloading.

Linear gradients are prepared using gradient makers. Many configurations of gradient maker are available. The simplest gradient makers consist of two vessels of equal cross-sectional area joined by a connecting channel with a stopcock. One chamber is a reservoir and the other chamber has a mixing device and an exit connected to the centrifuge tube. There are two methods for preparing linear gradients:

1. The reservoir contains the less dense solution, the mixing chamber contains the denser solution, and the gradient is routed to the wall of the centrifuge tube at the top. This method is readily applicable to centrifuge tubes made of hydrophilic materials such as cellulose nitrate and cellulose acetate butyrate.
2. The reservoir contains the denser solution, the mixing chamber contains the less dense solution, and the gradient is routed to the bottom of the centrifuge tube. This method can be applied to any type of centrifuge tube and it is much easier to prepare the gradient without disturbance.

The gradient should be prepared and maintained at 4°C.

Preparation of Sample

The sample should be ready for loading before the gradient is prepared and should be kept cold for many preparations. The sample is usually prepared in the same buffer as the gradient. In addition, several points are important in sample preparation:

1. The sample solution must have a density less than that of the gradient.
2. Gradients should be centrifuged as soon as possible after the sample has been loaded to prevent so-called droplet sedimentation.
3. For optimal resolution in rate-zonal centrifugation, the sample must be loaded on to the top of gradient and the sample volume should not exceed 2–3% of the gradient volume.

Loading of the sample on to the density gradient is one of the most crucial steps in rate-zonal centrifugation. The simplest method is to use a pipette to load the sample directly to the meniscus at the tube wall.

Conditions During Centrifugation

Smooth acceleration and deceleration are important for all gradient work. In addition, control of the temperature of the sample and gradient are important for reliable and reproducible sedimentation. Fortunately, most modern ultracentrifuges are equipped with programmed acceleration and deceleration modes which minimize the disturbance of gradient and temperature control. It should be emphasized that, during the gradient reorientation phase of a run using a swinging-bucket rotor, the rotor should be accelerated as slowly as possible up to 1000 rpm, and the brake switch should be off below 1000 rpm during deceleration.

Recovery of Fractions from the Gradient

After centrifugation, gradients are fractionated to recover protein bands. Great care must be taken at this stage to avoid loss of resolution. Several points should be emphasized.

1. All operations should be designed to minimize disturbance of the gradient.
2. The volume of the tubing from the gradient to the fraction collector should be minimized.
3. Care must be taken to avoid contamination of the recovered fractions by pelleted materials.
4. The gradient should be fractionated at a slow flow rate, particularly if viscous materials are used for the gradient.

In order to collect the entire gradient in a series of fractions, several methods may be applied. The simplest is to pierce the bottom of the tube with a needle, and collect the gradient as it drops out. Another method is to pump the gradient from the bottom of the tube with a narrow capillary tube. However, this method is not recommended because of the potential to disturb the gradient and resulting loss of resolution.

Introduction

The first protein crystals described in the literature were obtained by Hünefeld in 1840. Hünefeld observed hemoglobin crystals after slow drying of blood pressed between two slides of glass. It is remarkable that this first result demonstrated the basic principle used today, that protein crystals similar to inorganic crystals may be produced by concentration of a protein in solution through slow dehydration. Throughout the history of protein crystal growth, the rationale for protein crystallization has been, firstly, separation of proteins from complex extracts, and then, starting in the 1930s, as purification as determination of the three-dimensional structure of protein molecules.

Knowledge about the three-dimensional structure is necessary to better understand the functions of protein molecules in living systems and plants. Three-dimensional structure can be determined by X-ray diffraction. For X-ray diffraction, good quality protein crystals of appropriate sizes are required. Crystal sizes in each direction should be at least 0.1 mm, if using a strong beam of synchrotron radiation, or at least 0.3 mm for conventional sources of X-rays.

Protein molecules in the crystalline state are more stable than in solution. Therefore, crystallized pro-

teins are more stable against denaturation and may be preserved for a significantly longer period of time than in solution. That is the reason that protein crystallization is often directed as much on preservation as on separation and purification.

This article comprises a brief description of general principles of protein crystal growth and a description of various techniques of protein crystallization with the emphasis on methods using a small amount of a crystallizing solution, from about 1 to 20 μL . The consumption of small amounts of protein is of value, since screening and optimization tests of determination of crystallization conditions typically require many portions of protein solution.

General Principles of Protein Crystallization

Intermolecular Interaction

To crystallize a protein it should be first of all dissolved to give a solution where the protein molecules become close one to another to create a nucleus that grows into a crystal.

An essential feature of protein solutions, associated with the complex structure and large size of protein molecules, is that the molecules may be charged by electric charges, of the same polarity, resulting in long-range electrostatic repulsion. This peculiarity is mediated by the ability of macromolecules to acquire protons from a solution or give up protons into the solution depending on the pH. The charge value of

protein molecules increases with the difference between pH of the solution and pH in the isoelectric point, pI , of the solution. At $pH = pI$, molecules become neutral, and accordingly, the long-range repulsion is absent. For most proteins pI is in the range 4.5–6.0.

At short distances van der Waals forces of attraction act between molecules. Competition between repulsion and attraction determines the state of protein molecules in solution. If the repulsion dominates, molecules remain apart in solution, protein is dissolved and no clusters or crystals are created. If attractive forces dominate, the molecules gather into clusters, that may form nuclei to yield crystals. For creation of well-ordered nuclei the attractive forces should be strong enough to provide slow clusterization but not so strong as to impair the formation of the crystal structure.

The Coulombic repulsive forces are affected usually by an addition to the protein solution of buffers, salts, precipitants and other additives. Buffers influence acidity; the pH of the solution alters the difference between pH and pI . This in turn changes charge values of protein molecules and accordingly the long-range repulsion. There are various buffers providing different pH: 0.1 M sodium acetate, pH = 4.6, 0.1 M trisodium citrate dehydrate, pH = 5.6, 0.1 M sodium cacodylate, pH = 6.5, 0.1 M HEPES, pH = 7.5, 0.1 M tris hydrochloride, pH = 8.5, etc.

Salts added to a protein solution may screen the repulsive interaction between the molecules. For instance, a 0.1–0.2 M aqueous solution of sodium chloride essentially shields the repulsive electrostatic forces. Precipitants such as polyethylene glycol (PEG) of various molecular weights, isopropanol and sodium formate, decrease the solubility of protein, initiating creation of clusters or nuclei.

Nucleation

Nucleation is initiated by fluctuation of density in a system of atoms or molecules. Crystallization in protein solutions is initiated by protein concentration fluctuation in a solvent. In regions of higher concentration, molecules are associated in clusters because of smaller intermolecular distances thus increasing attractive forces. Generally, clusters may be stable or metastable.

Reduction of repulsive interaction between protein molecules is a necessary condition of nucleation peculiar to proteins and other macromolecular substances. But it is still not enough to create a stable nucleus which becomes a seed for crystal growth. The mutual position of protein molecules should correspond to a minimal energy to form thermodynamically stable nuclei.

Thermodynamic free energy of a cluster in solution consists of two parts: volume energy, ΔG_v , and surface energy, ΔG_s . The volume energy is negative, so that it stabilizes the cluster, but surface energy is positive tending to make the cluster unstable. Competition between these two parts of the overall free energy determines the stability of clusters. The total free energy of a cluster, $\Delta G = \Delta G_v + \Delta G_s$, depends on its size, r , so that $\Delta G = \Delta G(r)$. This dependence reveals a maximum at a critical size, $r = r_c$. At sizes larger than r_c clusters become a stable nucleus capable to grow as a crystal. At sizes less than the critical size, clusters tend to dissolve, since they are energetically unstable.

The critical nucleus size, r_c , decreases with an increase of the supersaturation of protein solution $\beta = c/c_{\text{sat}}$, since $\Delta G_v \sim -\ln \beta$ and accordingly $r_c \sim 1/\ln \beta$. Here c is the concentration of protein in solution and c_{sat} is the concentration of the protein in saturated solution. In other words, c_{sat} is the solubility of the protein. Consequently, nucleation may occur only at $\beta > 1$, i.e. at protein concentration, c larger than the concentration of saturated solution, c_{sat} . This condition indicates also that the chemical potential of a cluster is lower than the chemical potential of the solution, and accordingly the volume energy ΔG_v is negative. An increase of the supersaturation, β also reduces the maximum of the total free energy, $\Delta G(r_c)$, which should be overcome to create a stable nucleus, because $\Delta G(r_c) \sim 1/(\ln \beta)^2$.

Nucleation is affected by many other parameters, such as relative specific surface energy of protein crystals in solutions, temperature, mobility and substructure of protein molecules, impurities, rate of supersaturation, etc. That is the reason that nucleation of proteins is an important step in protein crystallization, which often requires many screening experiments.

Crystal Growth

A zone of lower concentration is formed around a nucleus after it starts to grow, consuming surrounding molecules. The difference between the protein concentration in the bulk of the solution and in the depletion zone becomes a driving force, transporting the protein molecules from solution to the growing crystal. This mass transport is realized generally by diffusion and convection due to gradients of protein concentration. Slow transport of the molecules is required to yield good quality crystals. This is achieved at low supersaturation and low rate of dewatering of the protein solution and by crystallization at lower temperatures, ~ 4 – 6°C .

Mechanisms of attachment of protein molecules to the lattice of growing crystals have been investigated

intensively in recent years with the atomic force microscope. It was demonstrated by Malkin *et al.* with several proteins, lysozyme, thaumatin, canavalin, catalase and apoferritin, that macromolecules grow by all surface integration mechanisms involved in the crystallization of small molecules. The protein crystals reveal growth on screw dislocations and by two- and three-dimensional nucleation.

A screw dislocation generates steps that propagate along the crystal surface. The steps contain kinks at the crystal surface into which molecules are incorporated, building crystal layers in a spiral fashion around the dislocation core. This mechanism is realized basically at lower supersaturations, about 1–1.5. At higher supersaturations, protein crystals grow typically by two-dimensional nuclei formed on the surfaces. Absorption of three-dimensional nuclei have also been detected. The three-dimensional clusters are developed into multilayer stacks or microcrystals.

Absorption of impurities may cause a cessation of growth of macromolecular crystals. Dubrin and Feher revealed parallel step trains on lysozyme crystal surface accounted for by impurities, impeding the subsequent crystal growth. Malkin *et al.* have detected surfaces of lysozyme crystals completely covered by impurity absorption layers resulting in the cessation of growth.

Methods of Crystallization

Proteins may initially contain a large amount of impurities, such as salts, other classes of macromolecules, denaturated molecules, solid particles and other contaminants impeding crystallization. Therefore, proteins should be purified for crystallization tests. The same applies to buffers, salts and

precipitants used in crystallizing solutions. Descriptions of preparation and handling of proteins for crystallization and methods of characterization of macromolecules can be found in Further Reading.

There are many methods, techniques and apparatus for protein crystal growth depending on configuration of experiment – hanging drop, sitting drop or crystallization in a capillary. The method used also depends on the way the solution is supersaturated: by vapour diffusion, liquid–liquid diffusion, dialysis, mixing with a precipitant, change of temperature, etc. Other factors include gravity conditions and mass transport in solution, crystal growth in microgravity, gel method, crystallization in drops and suspended in heavy liquids.

Hanging and Sitting Drop

A hanging or sitting drop comprising a solute protein, to be crystallized, with a crystallizing agent, is equilibrated against a reservoir solution containing the crystallizing agent at higher concentration than in the drop (Figure 1). The reservoir, a glass vessel, is closed by a glass cover slip and sealed by grease to prevent the liquids evaporating. The drop volume is usually from 1 to 10 μL , the volume of reservoir solution is $\sim 0.5\text{--}1\text{ mL}$. An increase of concentration of crystallizing agent in the drop leads to a supersaturation of protein solution necessary for crystallization. Equilibration is achieved by vapour diffusion of water or other volatile components and continued until vapour pressures in the drop and in the reservoir become equal.

The crystallizing agent may comprise a buffer, such as sodium acetate, tris hydrochloride, HEPES or sodium cacodylate, a precipitant, such as polyethylene glycol, isopropanol or sodium formate, and a salt.

Figure 1 Schematic presentation of hanging- and sitting-drop techniques. (A) Hanging drop; (B) sitting drop. (1) Drop of protein solution, (2) reservoir solution, (3) glass vessel, (4) coverslip, (5) sealing rim, (6) inverted glass pot. (From Ducruix and Giedge (1992) by permission of Oxford University Press.)

If there are no volatile components except water, diffusion of water occurs from the drop to the reservoir solution. This decreases the drop volume and accordingly increases the concentration of all the components. In the presence of a volatile species, such as isopropanol, in the crystallizing agent, diffusion proceeds in two directions, from the reservoir to the drop, and in the opposite way, from the drop to reservoir, of water. Equilibrium is achieved after the saturated partial vapour pressures of evaporating components become equal in the drop and in the reservoir. In this case, the drop may decrease or increase in volume or remain the same.

The often used ratio between concentrations of the crystallizing agent in the reservoir and the drop is 2. This is obtained by mixing equal volumes of protein solution and the reservoir solution. It may be, for instance, a mixture of 2 μL of the reservoir and 2 μL of the protein solution in the hanging or sitting drop. If only water diffusion takes place in the absence of other volatile species, at equilibrium the final volume of the drop will be half the original volume. Accordingly, concentration of all components in the drop, protein, buffer, salt and precipitant double.

Nucleation and crystal growth in a drop are affected essentially by rate of equilibration. The rate depends on the difference between vapour pressures in the drop and reservoir, which in turn depends on the content of the crystallizing agent, temperature, and the size and shape of the drop. Significantly lower equilibration rates with polyethylene glycol rather than ammonium sulfate as a precipitant have been demonstrated. A decrease of equilibrium rate with increase in drop size and with decrease of temperature has also been revealed. The time for $\sim 90\%$ equilibration varies from a day to about one month.

In the hanging-drop technique, crystals are basically created at the bottom of the drop, near the surface. This may be caused by forming a layer of supersaturated protein solution near the surface during evaporation of water. The subsequent distribution of protein concentration over the whole drop is diffusion limited.

The contribution of convection is small, since the supersaturated layer is of higher density and located at the bottom of the drop. Such inhomogeneity applies to nucleation as much as to crystal growth.

In the sitting-drop, distribution of protein concentration is different. Evaporation forms initially a layer of higher concentration near the surface at the top. This excessive concentration is then distributed quickly over the drop by convection. Accordingly, nucleation and the start of crystal growth occur practically at the same protein supersaturation. This is a disadvantage in comparison with the hanging-drop

technique, since crystals grow at higher supersaturation. From another point of view, however, the sitting-drop method is energetically more favourable and heterogeneous nucleation on various substrates, including minerals can take place.

For screening and optimization tests, multichamber plates are utilized, containing many wells of the type shown in Figure 1. Plastic Linbro boxes, normally used for tissue culture, are convenient for hanging-drop tests. Each such box contains 24 wells. To prepare tests, about 0.7–1.0 mL of crystallizing agent is put in each reservoir. A drop comprising a mixture of protein solution and reservoir solution is placed on the glass coverslip. Then, the coverslip with the drop is gently turned over and set on the vessel rim covered with a thin layer of grease. In a similar way, the sitting-drop tests are prepared, with the difference that the drop is placed on an inverted glass pot (Figure 1).

Method for Crystal Growth in a Capillary

A vapour diffusion method for growing crystals inside capillary tubes, invented by M. Y. Gamarnik and U. R. Alvarado, is illustrated in Figure 2. The crystallizing unit comprises a capillary tube containing a column made up of three layers. The first layer is a protein solution to be crystallized, which may contain a buffer, salt, precipitant and other additives. The second layer is an absorbent, which is typically a liquid, such as glycerol or a highly concentrated salt solution. In the preparation of the crystallizing unit, the protein solution and absorbent are placed in the capillary tube so that they are segmented by an air section. The ends of the capillary tube are sealed by end-caps. The liquids are placed sequentially in the capillary tube by a syringe. The lengths of the protein solution, absorbent and air layer segments are selected by experimenter, but the usual lengths are from 2 to 20 mm.

The internal diameter of the capillary tube is selected so that the capillary forces, acting on the liquids, held within the sealed tube, are sufficient to prevent direct contact between the liquids during handling or transportation. The internal diameter is usually less than 3 mm, but for crystallization tests from about 1–10 μL of protein solution the diameter should be about 0.6–1.5 mm.

The vapour of the solvent, which is normally water, diffuses from the protein solution through the air layer to the absorbent because of the difference in the water vapour pressures in the protein solution and absorbent. Evaporation of water from crystallizing solution results in an increase of concentration of protein and other components – buffer, salt and

Figure 2 Schematic presentation of vapour diffusion method for crystal growth inside a capillary tube. (A) Initial configuration, (B) final configuration. (1) Capillary tube, (2) protein solution, (3) absorbent, (4) air layer, (5) end-caps, (6) protein solution with grown crystal, (7) absorbent containing absorbed water.

precipitant – which were initially present. Nucleation and growth of a protein crystal occur within the crystallizing solution after it reaches the appropriate supersaturation.

During the vapour transport, the length of the air layer remains approximately constant but shifts toward the crystallizing solution. The length of the protein solution layer decreases. Accordingly, the length of the absorbent, containing absorbed water, increases (Figure 2B). At any time during crystal growth, it is possible to calculate the concentration of protein and other additives in the protein solution by the relative change of its length.

A desired rate profile of water evaporation can be set by appropriate choice of concentration and volume of the protein solution and absorbent, the length of the air layer and the temperature. Often it is desirable to set a relatively rapid rate of evaporation during the initial phase of the growth process leading to nucleation, followed by a lower rate of evaporation during the crystal growth process. To accomplish this profile, the air layer length should be small, about 3–5 mm, and the absorbent layer length should be also small, in comparison with the length of protein solution layer. The short air layer establishes a relatively fast dewatering followed by a rapid increase of concentration of protein solution, while the small volume of absorbent allows a relatively rapid decrease in the rate of evaporation after the initial phase of evaporation, due to dilution of the absorbent by the absorbed water. This profile, initiating nucleation with subsequent slow crystal growth, usually yields a single crystal or a few crystals in each portion of the protein solution. This is beneficial since the dissolved protein feeds only one or a few crystals during the growth, resulting in their larger size.

Liquid–Liquid Diffusion Techniques

Interface diffusion In the interface-diffusion method for protein crystal growth two liquids – a protein solution and a solution of the crystallizing agent – make contact and are separated at an interface. Equilibration is achieved by diffusion of the crystallizing agent and protein across the liquid–liquid interface. Diffusion leads to a slow increase in the concentration of the crystallizing agent in the protein solution near the interface. Nucleation occurs in the interface region after sufficient supersaturation. Subsequent slow crystal growth is provided by the relatively small interface region of the higher protein supersaturation.

A basic difficulty in this technique is bringing the liquids into contact without convection, i.e. without rapid mixing. Convection may be reduced if the less dense solution is gently placed on the more dense solution. Crystallization experiments conducted under microgravity conditions in space avoided convection during solution contact when the interface-diffusion technique was used.

To use only a small amount of protein solution, about 2–20 μL , the liquids may be brought into contact in a capillary tube of diameter in the range ~ 1 –2 mm.

Dialysis In the dialysis technique, the protein solution and crystallizing-agent solution are separated by means of a molecular membrane. Both solutions are in contact with the membrane, which allows diffusion of small molecules, but prevents macromolecules passing. The maximum molecular weight of molecules able to diffuse through the membrane pores is determined by the molecular weight cutoff (MWCO).

The MWCO of contemporary dialysis membranes is in the range from 100 to 300 000 Da.

During equilibration, molecules of buffer, salt, precipitant or water may diffuse through the membrane from the crystallizing agent to the protein solution and also in the opposite direction, resulting in crystallization. For micro-quantities of protein solution, capillaries of small internal diameters, about 1–2 mm are used. The protein solution is placed in a capillary, the end of which is capped by the membrane. The membrane end of the capillary is then put into an appropriate agent solution for crystallization.

Batch technique Microbatch techniques include crystallization under oil, with droplets of about 1–10 μL of crystallizing solution. It was demonstrated that application of paraffin and silicone oils affect the rate of equilibrium, resulting in a better quality of crystals. A containerless method has been developed, where the crystallizing solution drop is suspended between two oil layers of different density, preventing the undesirable contact of the protein solution with walls of a vessel.

A drawback of the batch method is that, typically, many nuclei are formed resulting in the growth of many crystals, and it takes much effort to find the conditions for growing just one or a few crystals in a single batch.

Gel Method

In the gel method, crystallization in a gel results in the protein solution being trapped by a loose network which is stretched over the whole volume of the solution. The gel comprises macropores, of about 100 nm in size, filled with the crystallizing solution. The macropores are interconnected, by a dense system of micropores, of about 10 nm in size.

Entrapping of the crystallizing solution by the gel network prevents natural convection and sedimentation. Accordingly, equilibration between the protein solution and the crystallizing agent is mediated by diffusion only, through the gel pores. This results in slow crystal growth, improving the quality of the produced crystals if no gel structure is incorporated in the crystal lattice, as is often the case. Various crystal growth techniques can be used with a gel, such as hanging-drop technique, liquid–liquid diffusion and dialysis. Silica gel and agarose gel are most often used for protein crystallization.

Crystallization in Microgravity

Protein crystal growth has been studied under microgravity conditions conducted in space (satellites and

space shuttles). Space-grown crystals are frequently of better quality than the same protein crystals grown on the earth. Under microgravity conditions, convection and sedimentation are suppressed. Accordingly, transport of molecules, supersaturating the protein solution, is mediated by diffusion only, providing slow crystal growth. Typically, crystals are suspended and grow freely in different crystallographic directions, forming a well-ordered structure and equilibrium shape.

Various methods have been used for crystal growth experiments in space, including interface-diffusion, dialysis and vapour diffusion. Most methods have a device or a means to connect or disconnect interaction between the protein solution and crystallizing agent so that mixing only takes place under zero gravity. Typically, two wells, one of which is filled with protein solution and a second one filled with crystallizing agent, are brought into contact in orbit through a connecting valve or by a relative movement of the wells.

Concluding Remarks

Experiments, directed at crystallization of proteins require an understanding of the main principles of nucleation and growth and need much testing. Some tests are associated with a decrease in critical supersaturation, necessary for nucleation, through selection of appropriate buffers, salts and precipitants or by exploration of substrates for heterogeneous nucleation. Other methods follow the development and use of crystallization cells, consuming small amounts of protein solution, through decreasing the internal diameter of capillaries (in the capillary method) or the size of droplets in microbatch and hanging-drop experiments.

Small volume crystallization cells will be adapted for microgravity experiments to reduce space requirements on satellites and shuttles, accordingly reducing their cost. This may be realized by modification of the capillary technique, shown in Figure 2. For instance, two air layers may be used instead of one, separated from each other by a water barrier layer. The water barrier layer delays absorption of the vapour from the protein solution until the barrier layer is eliminated by absorption into the absorbent. The necessary delay is typically one or two days, from preparation of the tests until the spacecraft carrying the crystal growth device has attained microgravity conditions.

Development of crystallization methods at lower critical supersaturation seems to be supported by a broadening of our knowledge of the main principles governing nucleation and growth of macromolecular crystals.

Transmissible spongiform encephalopathies are neurodegenerative diseases found in both humans and animals. The oldest known member of this family of diseases is scrapie in sheep and goats and the most infamous member is bovine spongiform encephalopathy or 'mad cow disease'. These diseases are fatal for the individuals who become infected. As a result, there is a considerable amount of interest in developing methods to detect early infection. This would enable removal of animals from food chains and by-products used for cosmetic and health care. For humans, an early diagnosis may make it possible to treat infected individuals with drugs to arrest the course of the disease.

A feature of these diseases is the accumulation of rod-shaped fibrils in the brain that form from an aggregated protein. This abnormal protein is a protease-resistant form of a normal host cell glycoprotein (prion protein). When the aggregated protein is denatured in sodium dodecyl sulphate (SDS) and β -mercaptoethanol, a monomer form of $M_r \sim 27$ kDa is observed. This abnormal prion protein is used as a marker for infection with a transmissible spongiform encephalopathy.

The abnormal prion protein is insoluble in most biological buffers, whereas the normal prion protein is soluble. In natural infections, the abnormal prion protein is found in very low concentrations. It is found in higher amounts in rodent-adapted strains of the disease. These properties of insolubility and low concentrations present quite a challenge for the development of analytical methods to detect this protein.

Most of the methods used to detect the prion protein are based on histological techniques and are used postmortem. Immunoassays can be used to measure the prion protein. Most of the antibodies that have been produced to the abnormal prion protein have been made to the denatured form. Removing these denaturants is a major problem in the development of immunoassays. Western blot can be used to detect the prion protein but cannot be easily automated. Some new approaches using chemiluminescence and time-resolved fluorescence in plate assays have been developed. The amount of prion protein detected by these assays is in the range of picomoles or > 500 fmol. To improve sensitivity, we have approached this problem using capillary electrophoresis with laser-induced fluorescence. Fluorescent-labelled peptides from immunogenic epitopes of the prion protein can be detected in the attomole range using this technique. A competition immunoassay using fluorescein-labelled peptides was developed which is

able to detect the abnormal prion protein in the low picogram range; this method can quantitate the amount of prion protein. This assay was based on the separation of the free peptide from the immunocomplexed peptide. Unlike most immunoassays which measure only the antibody-bound ligand, both the free and the bound peptide can be measured.

Method Development

Preparation of Tissues

Scrapie-infected tissues including brain, lymph node and buffy coats were obtained from sheep confirmed positive for abnormal prion protein by Western blot. Normal tissues were obtained from sheep from a scrapie-free flock and were confirmed negative by the above tests. Briefly, the tissues were weighed, and ground to a fine powder in liquid nitrogen. Buffy coats were prepared from blood and placed in 2 mL of 20 mmol L⁻¹ phosphate pH 7.0, 0.15 mol L⁻¹ NaCl, and frozen at -70°C until they were processed as the tissues. After grinding, the tissues were placed in 20 mmol L⁻¹ Tris pH 7.4, 0.15 mol L⁻¹ NaCl, 0.005 mol L⁻¹ MgCl₂ (10% w/v) and incubated at 37°C for 1 h in 50 µg mL⁻¹ DNase. After incubation with DNase the tissue homogenates were treated with proteinase K (50 µg mL⁻¹) for 1 h at 37°C and held overnight at 4°C. Sodium *N*-lauroyl-sarcosine was added to the homogenate to make the solution 10% in the detergent. The homogenate was incubated for 1 h at 37°C and then was centrifuged at 10 000 g for 20 min to remove particulates. The resultant supernatant fluid was centrifuged at 230 000 g for 1 h. The pellet was resuspended in 10 mmol L⁻¹ Tris pH 7.4 (250 µL g⁻¹ of the initial brain sample). The sample was solubilized in 0.01 mmol L⁻¹ Tris HCl, pH 8 containing 2 mmol L⁻¹ ethylenediamine-tetraacetic acid 5% SDS and 10% hexafluoro-2-propanol at 100°C for 10 min.

Chromatography

To remove the SDS, the sample was applied to a poly-HYDROXYETHYL A (PolyLC, Inc., Columbia, MD, USA) high performance liquid chromatography column (200 × 4.6 mm) in 95% acetonitrile, 5% water containing 0.1% trifluoroacetic acid and 50 mmol L⁻¹ hexafluoro-2-propanol (buffer A). The flow rate was 0.5 mL min⁻¹. The conditions for eluting abnormal prion protein were buffer A for 8 min and then a linear gradient to 100% water containing 0.1% trifluoroacetic acid and 50 mmol L⁻¹ hexafluoro-2-propanol (buffer B) in 15 min, 100% buffer B for 10 min. Peak fractions were collected and dried in a vacuum centrifuge. Fractions were resuspended

in 10 µL of dH₂O and tested for abnormal prion protein in the capillary electrophoresis assay.

Peptide Synthesis and Antibody Preparation

Four peptides from the prion protein were synthesized. The peptide sequences were CGQGGGTHNQWNKPSL (spanning amino acid positions 89–103), CNDWED-RYYRENMYR (142–154), (CRYPNQVYYRPVDRYSNQNNFVHD (155–177) and RESQAYYQRGASVIL (218–232) (Multiple Peptide Systems, San Diego, CA, USA). The peptides were labelled with fluorescein through a γ -butyric acid linkage on the N-terminus during synthesis. The peptide 218–232 is used here as a representative sample.

Rabbits were immunized with each peptide and specific antibodies were produced for each peptide. These antisera reacted with scrapie-infected brain but not with normal brain on Western blot analysis. Rabbit IgG was prepared by passing each antiserum over an affinity column. Briefly, 10 mg of a peptide was coupled to agarose resin modified with an *N*-hydroxyl succinimide ester in 1.0 mL dimethyl formamide at room temperature for 20 min. After coupling, the resin was washed with 5 mL of 0.1 mol L⁻¹ 3-(*N*-morpholino)propanesulfonic acid (MOPS) pH 7.5 (column wash buffer). Unreacted ester groups were deactivated with 0.1 mol L⁻¹ *N*-(2-hydroxyethyl)piperazine-*N'*-(4-butanedisulfonic acid) (HEPES) pH 8.0 and 0.1 mol L⁻¹ NH₄Cl for 15 min. Before antibodies were applied to the peptide column they were purified using protein G chromatography. After diluting 1 : 2 in column wash buffer, the antibodies were then applied to the affinity column and recycled over the column for several cycles. The column was washed with column wash buffer and the antibodies eluted with 0.1 mol L⁻¹ NaH₂PO₄, pH 2.5 into tubes containing 50 µL of 1 mol L⁻¹ HEPES, pH 8.5. The absorbance was measured at 280 nm. Fractions with absorption at 280 nm were pooled, aliquoted and frozen at -20°C.

Immunocomplex Formation

Fifteen microlitres containing ~0.2–20 pmol of the fluorescent-labelled peptide were mixed with varying amounts (0.5–5 µg) of purified rabbit IgG to determine the antibody concentration that forms ~50% of the total immune complex formation. The final volume of the sample was adjusted to 20 µL with capillary running buffer. After mixing the components, the samples were incubated at 25°C for ~10 min and at 4°C overnight. The height of the immune complex peak was measured and replicate samples of the peaks varied less than 1%. Slight changes in the antibody reactivity, temperature and

Figure 1 A chromatogram showing hydrophilic interaction chromatography on poly-HYDROXETHYL A. The peak that was positive for abnormal prion protein (PrP) is indicated. The gradient conditions for running the column are shown by the dashed line.

preparation of the running buffer caused small variations in the height of the immunocomplex peak from day to day. Known concentrations of unlabelled peptides corresponding to the fluorescent-labelled peptides were used to generate standard curves.

Free Zone Capillary Electrophoresis

Free zone capillary electrophoresis was performed on a Beckman P/ACE 5500 controlled by P/ACE Station software. Laser-induced fluorescence detection was

done using an air-cooled argon laser with excitation at 488 nm and emission at 520 nm. An unmodified capillary 20 cm (length to the detector) \times 20 μ m i.d., total length 27 cm capillary was used with a 200 mmol L⁻¹ Tricine buffer that was adjusted to pH 8.0 by 6 mol L⁻¹ NaOH. This buffer was selected after studying the effect of higher pHs and other concentrations of the buffer on the separation, immunocomplex formation and fluorescence. To prevent the abnormal prion protein from adhering to the

Figure 3 A plot of the peak height of the immunocomplex peak versus the amount of antibody added to the assay.

capillary walls, 0.1% *n*-octylglucoside (Boehringer Mannheim, Indianapolis, IN, USA) and 0.1% bovine serum albumin (Sigma Chemical Co., St. Louis, MO, USA) were added to the buffer. In preparation for separation, the capillary was rinsed for 1 min with 0.25 mol L⁻¹ NaOH, rinsed for 2 min with water and then rinsed for 2 min with buffer. The separating conditions were 30 kV for 3 min at 20°C with a current of ~20 μ A. The sample was injected for 15 s followed by a 5 s injection of running buffer. The sample volume was ~0.95 nL. Rinses were carried out under high pressure and sample injection carried out under low pressure.

Results

Hydrophilic Interaction Chromatography

Figure 1 shows a chromatogram of the results of hydrophilic interaction chromatography. This chromatography removes the SDS and other interfering compound so that the reproducibility of the assay is improved.

Capillary Electrophoresis Immunoassay

By the addition of fluorescein at the amino terminal during synthesis, the sensitivity of this assay is enhanced 100-fold relative to the chemical addition of

Figure 4 Plot of the ratio of the height of the immunocomplex peak/height of the free peptide peak versus the amount of unlabelled peptide added to the assay.

Figure 5 Representative electropherograms of antibody control (continuous line), normal brain sample (dotted line) and scrapie-infected brain sample (dashed line).

fluorescein after synthesis of the peptide. An electropherogram showing the peptide and the immunocomplex peak when antibody is added to the assay is shown in **Figure 2**. A titration curve of antibody amount versus the height of the immunocomplex peak is shown in **Figure 3**. The amount of antibody that binds ~50% of the fluorescein-labelled peptide was chosen as the amount to be used in the competition assays of the abnormal prion protein with the labelled peptide for binding sites on the specific antibody. Competition is determined by measuring the ratio of

the height of the immunocomplex peak and of the free peptide peak. A standard curve was determined by adding known amounts of unlabelled peptide into the assay. This curve is shown in **Figure 4**. Electropherograms representing the immunocomplex peak, a preparation from a normal sheep and a preparation from a scrapie-infected sheep are shown in **Figure 5** (peptide 218–232). An electropherogram representing a sample from a lymph node of an infected sheep is shown in **Figure 6**. **Figure 7** depicts three electropherograms showing the antibody control,

samples extracted from buffy coats of a normal sheep and from a buffy coat of a scrapie-infected sheep.

Concluding Remarks

The capillary electrophoresis assay described in this study is reproducible, more sensitive and faster than other analytical tests. The samples used in the capillary electrophoresis assay were obtained from brain and the lymphoid system of the animals. The sensitivity of this assay made it possible to test samples from other tissues that contain much less abnormal prion protein than brain samples. This assay has the potential to use tissues and fluids from live animals and diagnose animals prior to the onset of clinical signs of disease. Automation of this test could lead to more economical and efficient methods for testing for abnormal prion protein.

Field Flow Fractionation

R. Hecker and H. Cölfen, Max-Planck-Institut für Kolloid und Grenzflächenforschung (Kolloidchemie), Am Mühlenberg, Golm, Germany

Copyright © 2000 Academic Press

Introduction

This review focuses on the use of field-flow fractionation (FFF) for the characterization of proteins and protein assemblies such as protein aggregates, DNA

and viruses. FFF is based on the differential transport rates of solutes in a ribbon-like channel when interacting with an applied field. The type of field may be chosen from a wide range, for example an electrical potential, sedimentation, a hydrodynamic cross-flow, a thermal gradient and so forth. A schematic of this is shown in **Figure 1**. The solute will therefore occupy a region above the sample wall, with a mean position determined by the balance between the solute's diffusion and the sample-applied field interaction. Although there exist further complications for solutes greater than $\sim 0.5 \mu\text{m}$ diameter, they are not relevant given the small hydrodynamic diameter of proteins. Positioned at the outlet of the channel is a sample detector of some sort, typically a traditional high-performance liquid chromatography (HPLC) spectrophotometric detector, although a significant development has been with the application of a number of detectors providing complementary information about the sample. Such detectors include spectrophotometric and refractive index types, and more recently light scattering for molecular mass, electrospray-mass spectrometry, and inductively coupled plasma, although the last two have not yet been applied to protein studies.

There are a number of advantages offered by the FFF methods over other contemporary protein analysis methods. FFF is often more rapid than analytical

ultracentrifugation, and the range of fields available provide FFF with greater versatility. In comparison with gel-permeation chromatography, FFF is not impeded by a size exclusion limit, the low exposed surface area limits sample loss through adsorption on to the exposed surface, and the availability of field programming allows a wide range of materials to be analysed in a single channel. The open channel geometry usually allows FFF to characterize samples without need for pretreatment, such as filtration, and provides a very high upper limit to the protein size range. Similarly, the open channel allows the theoretical basis of FFF to provide direct access to fundamental physical constants of proteins, often without the need for calibration. Finally, both FFF and gel electrophoresis may separate a protein mixture, but sample collection is simpler in FFF.

Flow FFF

The 'universal' nature of (cross)-flow FFF (Fl-FFF) has led to its wide use for protein characterization. The free choice of carrier liquid, whether a buffer or a simulated native environment, avoids denaturing the protein. Flow FFF has two configurations, the original symmetric form and the newer asymmetric method, differing only how the field is generated in the fractionation cell and sample-loading protocols.

Figure 1 (A) Schematic of the mechanism of FFF separation of proteins. The smaller protein, with greater diffusivity, competes more successfully with the applied field and occupies a mean position further from the accumulation wall. Samples occupying the higher mean position is subject to more rapid flow laminae, and elutes earlier. The particle sizes represented, the channel thickness and the extent of back-diffusion are not to scale. (B) For the subtechnique flow FFF, the accumulation wall is a liquid-permeable porous material, typically ceramic. A membrane exists over the accumulation wall to prevent the samples from leaving the cell through this wall. The upper wall may or may not be porous as well, depending whether the symmetrical or asymmetrical variant is used.

Table 1 Compilation of flow FFF physicochemical data relevant for selected common proteins and with comparison to commercial polystyrene latexes

Sample	Molecular mass (Da)	Diffusion coefficient ($\times 10^{11} \text{ m}^2 \text{ s}^{-1}$, $\times 10^7 \text{ cm}^2 \text{ s}^{-1}$)
Cytochrome c (bovine heart)	13 400	11.4
Ovalbumin (chicken egg)	45 000	8.71
Bovine serum albumin	64 000	6.89
Catalase (horse liver)	221 000	4.30
Apo ferritin	450 000	3.84
Urease	483 000	3.46
Ferritin	622 000	2.91
Tobacco mosaic virus	$\approx 40\,000\,000$	0.46
Polystyrene latex, \varnothing 0.090 μm		0.45
Polystyrene latex, \varnothing 0.311 μm		0.22

In both cases, the separation is a direct function of the diffusion coefficient, where the most highly diffusive components are the least retained. A compilation of common biological samples and their diffusion coefficients are provided in **Table 1**.

FI-FFF is capable of separating proteins with only a 15% size difference within 3–10 min. Reported results for animal proteins and biopolymers include albumins (human and bovine serum, egg), globulins (γ -globulin, haemoglobin, thyroglobulin), ferritin, apoferritin, lysozyme, casein, blood products (human and rat blood plasmas, lipoproteins) and nucleic acids. Proteins from an industrial perspective are represented by a growing body of work emerging on the characterization of proteins from flours used for bread-making purposes.

In all of the above cases, no sample treatment is needed prior to injection, such as exhaustive dialysis or filtration. This is to be expected, as the permeable membrane acts as a dialysis cell, and the open channel will not become clogged and require a filter. Since the sample is not manipulated beforehand, the presence of aggregate structures remains unaltered. **Figure 2** shows baseline resolution of a biological mixture. Protein dimers elute as satellite peaks at ~ 1.4 retention times of the monomer, followed similarly by the higher aggregates eluting later. Most significantly, the entire separation takes place in only four minutes.

The asymmetric flow FFF variant does not inject the sample directly into the inlet line. Rather, a sample pump introduces the sample into the cell and opposing flows from both ends of the cell hydrodynamically focus the sample into a narrow band across the channel before elution. This allows for remarkably well-resolved and efficient protein separations. **Figure 3** illustrates the sensitivity of the technique. Two plasmid fragments were injected at low concentration ($0.1 \mu\text{g } \mu\text{L}^{-1}$) and volume ($1 \mu\text{L}$) while exhibiting both baseline resolution and elution in less

than 15 min. One further advantage of the focusing method is the immobilization of the sample prior to elution. For a very dilute sample, multiple injections subject to these opposing flows produce an on-channel concentrating effect, where the protein is retained on the membrane at the focus point.

During any form of chromatography, sample dilution is inevitable. For small quantities of proteins this may challenge the limits of the detectors used. FFF offers an advantage over other methods through the ability to skim off the atmosphere of carrier liquid and greatly reduce sample dilution before detection. Sample enhancement was first mentioned in the literature in the early 1990s and now enjoys routine use in

contemporary practice. Both symmetrical and asymmetrical variants have been successfully applied to proteins. Of special interest is the frit inlet–frit outlet modification. These methods in tandem enhance detectability and aid fractionation stability. The combination of frit inlet and outlet has been reported as recently as 1999, for the automation of wheat protein fractionation.

One rarely discussed drawback to the FI-FFF method is the requirement of a membrane for sample retention. For adhesive protein samples, this demands compatibility between the sample, membrane and the carrier solution. Biopolymers can strongly adsorb on to particular membranes and at modest ionic strengths may be completely adsorbed. The simplest method to test this is to inject samples over a range of concentrations and/or volumes and ensure there is

proportionality between detected signal size and the amount of sample. A partial, reversible adsorption leads to an increased retention and this would indicate that the sample is erroneously large, or induce a number of fractionation profile artefacts. Clearly the chemistry of the system, between the sample, membrane and carrier, must be known before any statements may be made.

The membrane's physical characteristics may also be significant. Firstly, membrane compressibility and protrusion into the channel reduce the channel thickness and elution is more rapid, although this is easily detected by measuring the channel void volume with an unretained probe. More subtle effects include surface roughness and membrane pore size, as demonstrated by **Figure 4**. Although the experimental arrangement, carrier sample chemistry and flow rates are the same for both experiments, the effect of the membrane is clear. The molecular mass of cytochrome c is only just greater than the membrane size cut-off (12 500 versus 10 000), and the delayed retention from the poor membrane may be attributed to a partial physical entrapment in the pores. For the poor membrane the pore size distribution may be particularly wide, leading to a greater proportion of the sample suffering excessive retention. The mean size and size distribution of the pores of the membrane are clearly an issue of importance. A simple solution is to choose a much finer membrane, for example a cut-off at 3000 or 5000 is appropriate for cytochrome c, but the pressure drop across the channel may be incompatible with high field flow rates needed for sufficient retention of small species. The

Figure 4 Superposition of two elution profiles for cytochrome c (0.82 mg mL^{-1} , $25 \text{ }\mu\text{L}$) in 0.05 mol L^{-1} 2-[N-morpholino]propanesulfonic acid ('mops') buffer at pH 6.2. The membranes are both regenerated cellulose, with cited 10 000 molecular weight nominal pore sizes from different suppliers. From Hecker, unpublished results.

presence of the membrane therefore determines the smallest-sized species capable of being retained in a FI-FFF channel.

Such membrane effects have been used to advantage, however. Proteins have been characterized with a separation based on both standard FFF principles and enhanced retention for some species by sample-membrane interactions. This offers a remarkably wide scope for characterizing systems with subtle differences in physical sizes but dissimilar chemistries, but assigning peaks in the fractionation profile calls for a number of pure standards and calibration processes.

Of particular interest to protein science is the observation and quantification of protein-ligand or protein-protein interactions. Such an example is provided in **Figure 5** for the interaction between immunoglobulin IgG and an interacting ligand, polyglutamic acid, with the conjugate peak showing a small amount of free ligand. Quantifying such an interaction to measure the binding constant is a more difficult task. It is necessary to be able to produce fractionation profiles of the components as a function of concentration, implying that sample loss on to the membrane must be prevented. Furthermore, at least two from the protein, ligand or complex peaks must be well separated for quantification if the stoichiometry is known prior to the experiment, otherwise all three must be resolved. This precludes

many simple systems, for example bovine serum albumin (BSA)/anti-BSA, or ovalbumin/concavalin A, where the hydrodynamic sizes of these species are too similar for reliable quantification.

The application for protein interaction studies is limited to processes in which the interaction time is insignificant compared to the transport time, effectively making protein studies with a kinetic barrier to interaction difficult. Further, the use of FFF to investigate sample-sample interactions has been criticized, in that during transport dilution will occur so equilibrium in the FFF channel will be different to that of the mixing conditions. These limitations are clearly not relevant for rapid, near-irreversible interactions.

The opportunity for the study of protein shape by FI-FFF is possible. Like other hydrodynamic methods, the information available from these methods renders them primarily as complementary methods to high resolution crystallography or magnetic resonance. Nevertheless, both theory and practice, discussed by Cölfen and Pauck, demonstrate that retention is a function of molecular shape (**Figure 6**), with the retention decreasing with the degree of asymmetry.

All these examples show that FI-FFF is a powerful technique for protein characterization, as it is both very rapid and requires only microgram or smaller amounts of sample. Future potential can be seen in the quantification of interactions between proteins. However, potential factors affecting the results and possibly producing artefacts, such as membrane-sample interaction or sample shape, must be considered when interpreting the results.

Figure 5 Elution profiles of the components of a protein-polymer ligand mixture, immunoglobulin IgG and polyglutamic acid, and their covalent conjugate. The fractionation of the conjugate suggests that a quantity of the polyglutamic acid remains unbound, and offers a method of determining the binding constants of such mixtures. (Reproduced with permission from Giddings JC *et al.* (1992) *Journal of Liquid Chromatography* 15: 1729 Copyright Marcel Dekker.)

Sedimentation FFF

The technique of sedimentation FFF balances the back-diffusion of the sample against sedimenting forces, a function of the sample's hydrodynamic diameter, density difference and the rotation rate applied. Sedimentation FFF offers significantly greater size-based sensitivity over FI-FFF, with a corresponding greater resolution. The method is also free of the complications arising from the membrane required by FI-FFF, although the possibility of electrostatic effects between the sample and cell cannot be ruled out. Unfortunately for protein applications, where the hydrodynamic diameters are of the order of a few nanometers and sample density is close to that of the buffering liquid, the rotation rate of the channel, and thereby the applied force field, must be high. None the less, successful application of the sedimentation FFF method to the characterization of biopolymers has been reported. The samples of interest tend to be among the larger biopolymers, and

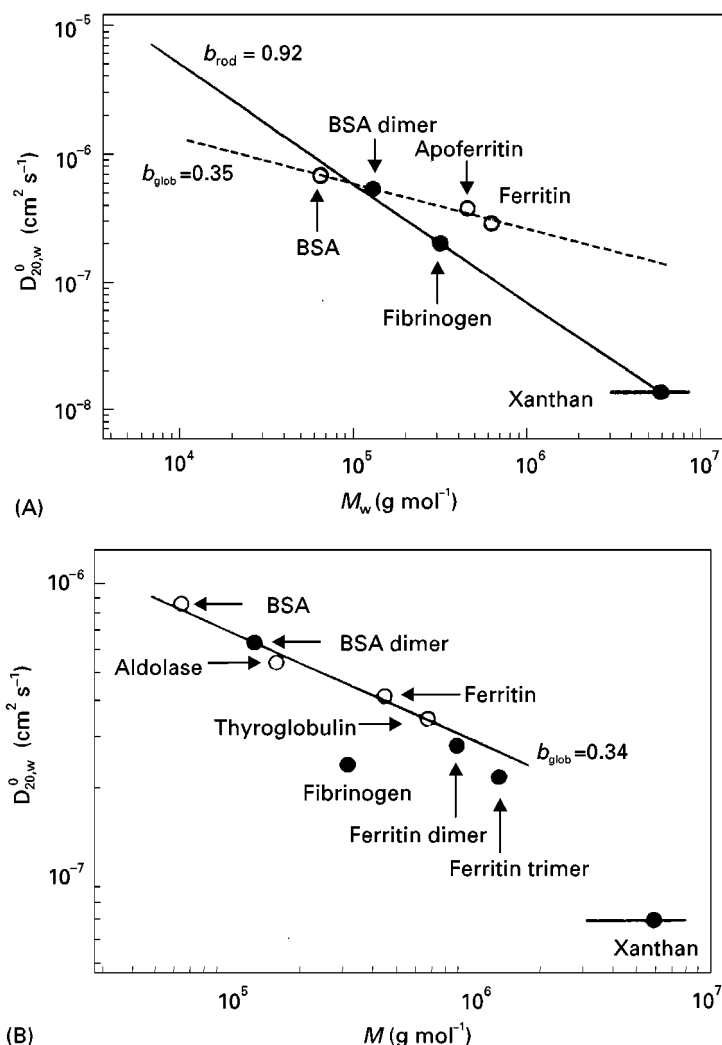

Figure 6 Temperature-corrected diffusion coefficients for a variety of proteins, using both analytical ultracentrifugation (A) and asymmetric FFF (B). The molecular weight–diffusion coefficient relationship is linear for the globular proteins, represented as open circles. Less spherical samples (filled circles) show a deviation from the linearity, with increasing deviation with eccentricity. (Reproduced with permission from Pauck T and Cölfen H (1998) *Analytical Chemistry* 70: 3886 Copyright the American Chemical Society.)

reported examples include DNA, proteoglycans, fibrinogen and myohemerythrin.

Thermal FFF

Thermal FFF, employing the Soret effect, is also suitable for the separation of biomolecules. Unfortunately, the thermodiffusion effect is extremely poor in water. The use of organic solvents restricts statements about the native state in aqueous-based buffer, and furthermore extensive conformational changes and even denaturation may occur which significantly restrict the range of applicable samples. Reported uses of thermal FFF for biological samples have been limited to the polysaccharides, dextrans, ficolls, pululans and cellulose, and the starch polymers amylose

and amylopectin, in dimethylsulfoxide as carrier liquid. Partially aqueous carriers have been investigated but it is the fraction in organic solvent that explicitly determines retention.

Electrical and Magnetic FFF

Electrical FFF is a subtechnique devoted to the fractionation of proteins, as reflected in the number of examples with protein applications. The narrow channel leads to high electrophoretic gradients across the cell, so samples with similar electrophoretic mobilities and differences in diffusion may be separated. As such, electrical FFF exists as a complement to electrophoresis. As early as 1972, a paper by Caldwell *et al.* first demonstrated the possibilities of

electrical FFF for the separation of albumin, lysozyme, haemoglobin and γ -globulin in buffer solutions at different pH.

Later, the performance of an electrical FFF channel with flexible membranes, a channel with rigid membranes and a circular channel for the separation of proteins was described. In these studies, human and bovine serum albumin, bovine γ -globulin, cytochrome *c*, egg white lysozyme and soluble ribonucleic acid (t-RNA) as well as denatured proteins were successfully separated. Unfortunately, the electrical field induces charge polarization of carrier liquid species, such that they migrated adjacent to the electrodes and then screen the electrical field. These early experi-

mental configurations of electrical FFF utilized ion-permeable membranes separating the channel volume from the electrode compartments. These conditions led to difficulties in forming a homogeneous electric field, and from the late 1970s the technique entered a period of quiescence. Results published in the early to mid 1990s using conductive, rigid walls of either graphite or gold-plated glass, have allowed reproducible separations, while the addition of a redox couple in the carrier liquid, such as quinone-hydroquinone, reduced the polarization effects. Due to these delays in experimental development, electrical FFF is less mature than other FFF techniques.

Electrical FFF is also well suited to measuring protein adsorption on to surfaces. The thin layer provides only subtle differences to the hydrodynamic size and net density, making flow or sedimentation FFF analysis difficult. However, the adsorption dramatically influences the surface charge and thereby influences both sample-field interaction and retention, as shown in Figure 7.

Although not formally FFF, dielectrophoresis in combination with fluid flow through an open chamber with interdigitated sinusoidally corrugated electrodes has been used for the separation of proteins and DNA.

A minor method, magnetic FFF, has been applied to study the retention behaviour of BSA in the presence and absence of nickel nitrate. In the presence of nickel ions, the retention time of the BSA sample was 6% higher with the magnetic field than it was without the field. Retention times reported for BSA samples both with and without a magnetic field did not differ in the absence of Ni (II). However, the application range of magnetic FFF for protein separations is very limited, and the method can only be applied in exceptional conditions.

Micropreparative FFF Applications

A variant of the FFF apparatus, the split-flow thin cell (SPLITT) permits continuous separation of milli- or even gram quantities of material. The apparatus is similar to a FFF cell equipped with both frit inlets and outlets. Initial configurations fed a mixture of large particles into the upper wall and carrier liquid into the base, while at the other end of the cell the liquid flowed out of two opposing exits. The ratio between the flows produces a hydrodynamic 'splitting plane' in the cell. During passage the larger particles could sediment sufficiently to exit at the other end of the SPLITT cell through the base, while smaller, less dense particles did not pass the splitting plane and eluted through the top. For protein applications, an electrical potential applied across such a cell in a range of buffers allows proteins with greater

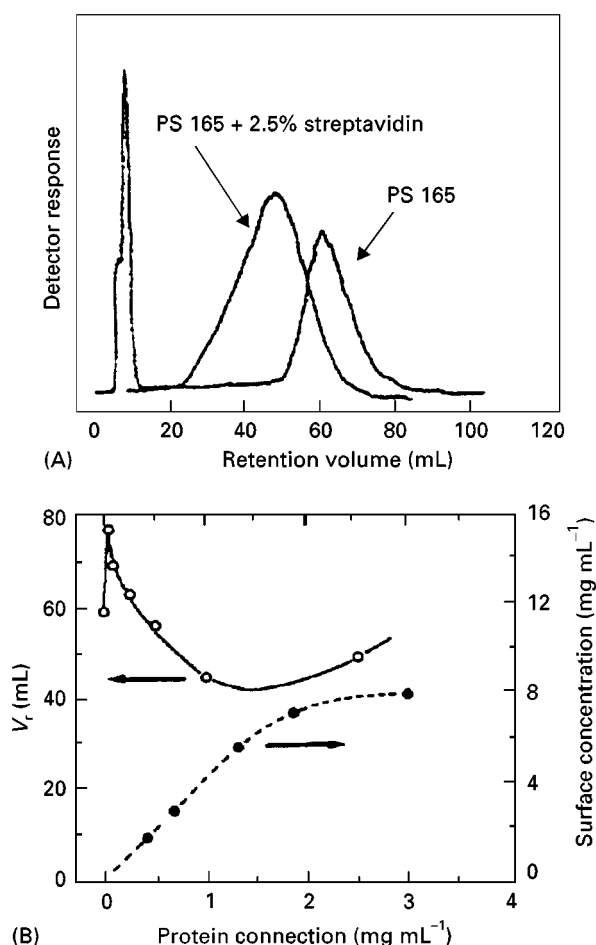

Figure 7 The coating of streptavidin on to a standard 165 nm diameter polystyrene (PS) latex bead affects the elution of the latex substrate by electrical FFF. Under pH 7.2 fractionation conditions the latex has a negative surface charge while the protein is isoelectric. The lower net surface potential is reflected in the poorer retention of the coated bead (A). The magnitude of this peak shift quantifies the degree of surface coating, as shown by the correlation in retention with the protein adsorption isotherm (B). (Reproduced with permission from Schimpf and Caldwell (1995) *American Laboratory* 27: 64–68.)

electrophoretic mobility to pass the splitting plane. The separation of a mixture of model proteins by such a method has been reported. The relatively high throughput reported (15 mg h^{-1}) makes this an interesting development for routine purification, but it requires a difference in protein pI of about two units as a necessary precondition for separation.

Miniaturization of FFF

There is a drive to produce the equivalent of hand-held devices for sample analysis based on the FFF principles, the chip laboratory. Advantages of such methods include the ability to analyse freshly sampled, or to undertake a number of simultaneous parallel analyses. For such miniaturized devices the injection volume is a significant proportion of the channel volume, with commensurate band-broadening problems, while theory predicts that some quantities, such as retention ratio and plate height, degrade with decreasing size. None the less, the reported developments for microfabricated electrical and dielectrophoretic FFF show healthy progression.

Concluding Remarks

The early development of FFF was hindered by the experimental complexity of the method and a focus on theory over practice. Over the last ten years, a number of simplifying experimental features such as the frit inlet-outlet system, and a fuller understanding of the theoretical background have led to a dramatic worldwide rise in the number of applications. It seems unlikely that more novel fields will be introduced into this family of techniques, but the subtlety of application is increasing. Methods and procedures are developing, from the analysis of simple proteins and mixtures, to protein aggregates,

proteins in complex matrices and increasingly fragile samples such as liposomes, where the open channel has few, if any, real analytical competitors.

The other exciting branch of development is increased commercial application, where the FFF method becomes a 'black box' technique. Leading the way is the FI-FFF method, but with the recent innovations in electrical FFF, the dominance of gel electrophoresis for protein analysis may be passing.

Introduction

Countercurrent chromatography (CCC) is essentially a form of liquid–liquid partition chromatography. Its unique feature among other chromatographic systems is derived from the fact that the method uses no solid support and the stationary phase is retained in the column with the aid of gravity or centrifugal force. The method has been termed after two classic partition techniques – countercurrent distribution and liquid chromatography.

A great advance in the CCC technology was made with the discovery of a new hydrodynamic phenomenon in a rotating coiled tube, which provided the basis for developing a highly efficient CCC system called high-speed CCC (HSCCC). In the last decade, types XL, XLL, XLLL and L cross-axis coil planet centrifuges (CPCs) have been developed to perform CCC with highly viscous polar solvent systems, such as polyethylene glycol (PEG) potassium phosphate, PEG dextran aqueous–aqueous two-phase systems. The absence of a solid support eliminates various complications that might arise from this in conventional chromatographic systems and the CCC has the ability to preserve the functional and enzymatic activity of proteins.

Apparatus

The cross-axis coil CPCs, which include types X and L and their hybrids (see Figure 3 in the article on Countercurrent chromatography), are used for protein separation. These modified versions of the

HSCCC centrifuge have a unique feature among the CPC systems in that the system provides reliable retention of the stationary phase for viscous polymer-phase systems. Figure 1 shows five different types of cross-axis CPCs. A series of studies has shown that the stationary-phase retention is enhanced by laterally shifting the position of the coil holder along the holder shaft, apparently due to the asymmetry of the laterally acting force field between the upper and the lower halves of the rotating coil. The degree of the lateral shift of the coil holder is conventionally expressed by L/R , where L is the distance from the middle point of the rotary shaft to the coil holder and R is the distance from the centrifuge axis to the holder axis. Types XL, XLL, XLLL and L have been effectively used for protein separations with various polymer-phase systems. For example, the polymer-phase system composed of PEG and potassium phosphate has a relatively large difference in density between the two phases, so it can be retained in XL–XLL column positions which provide efficient mixing of the two phases. On the other hand, the viscous polymer-phase system composed of PEG and dextran has an extremely low interfacial tension and small density differences between the two phases so that they tend to emulsify under vigorous mixing. Therefore, the type XLLL or L column position, that provides less efficient mixing under a strong centrifugal force field, is required to achieve satisfactory retention of the stationary phase for this polymer-phase system.

Figure 2 shows the XLLL cross-axis CPC ($L/R = 3.5$) equipped with a pair of multilayer coil separation columns. Each column consists of 2.6 mm i.d. polytetrafluoroethylene (PTFE) tubing wound on to a coil holder hub, forming multiple layers of left-handed coils. Table 1 lists various CPC models that have been used for the preparative separation of proteins, together with various parameters, including the

dimensions of columns and column holders, and β values of multilayer coils.

Polymer-phase Systems for Preparative Separation of Proteins

CCC utilizes a pair of immiscible solvent phases pre-equilibrated in a separatory funnel where one phase is used as the stationary phase and the other as the mobile phase. There are two typical polymer-phase systems available for protein separation: PEG dextran and PEG potassium phosphate systems.

PEG Dextran Systems

The polymer-phase system composed of PEG and dextran has a characteristic feature: small molecules are partitioned fairly evenly between the two phases,

whereas macromolecules such as DNA and polynucleic acids are distributed unilaterally in one phase or the other, depending on the pH of the solvent system. Consequently, the system can be used effectively for separation of these macromolecules using pH gradient elution. The PEG dextran system forms two layers without addition of high salt concentration, which tends to be precipitated in PEG phosphate systems (see below) at high salt concentrations. On the other hand, the PEG dextran system has a serious drawback in its CCC application. At high dextran concentrations the viscosity of the lower phase increases, and the similar polarity of the two polymers reduces interfacial tension between the two phases, resulting in a high probability of emulsification. A typical PEG dextran polymer system contains 4.4% (w/w) PEG 8000, 7% (w/w) dextran T500 and 10 mmol L^{-1}

Table 1 Type of apparatus and dimensions of columns used for protein separation

<i>x</i> -axis CPC	$(L/R)^a$	Coil holder		Columns

5	16.0	10.4	2.1	8.0
6	16.0	8.33	4.17	7.3
7	16.0	6.25	6.25	6.8

potassium phosphate buffer at proper pH. This two-phase system consists of a PEG-rich upper phase and a dextran-rich lower phase.

PEG Potassium Phosphate Systems

The PEG potassium phosphate system is complementary to the PEG dextran system in that it tends to distribute low-molecular-weight compounds unilaterally in either the upper or lower phase while macromolecules such as proteins are more evenly distributed between phases. Consequently, once a suitable partition coefficient for the target protein is obtained, the system yields high-purity fractions al-

most free from contamination by low-molecular-weight impurities that either elute immediately after the mobile phase front or remain almost permanently in the column.

Table 2 shows the composition of seven different PEG 1000 potassium phosphate systems. The ratio of the monobasic and dibasic potassium phosphate determines the pH of the solvent system and the partition coefficient of the protein samples. In all these solvent systems, the upper layer is rich in PEG and the lower layer is rich in phosphate.

Profilin-actin Complex Purification from Crude *Acanthamoeba* Extract

Using the type L cross-axis CPC equipped with a pair of multilayer coils (130 mL capacity), profilin-actin complex has been purified directly from an *Acanthamoeba* extract with a polymer-phase system composed of 4.4% (w/w) PEG 8000, 7% (w/w) dextran T500 at pH 6.8. The lower dextran-rich phase was used as the stationary phase. The sample solution was prepared by adding the correct amounts of PEG 8000 and dextran T500 to 12.5 g of the *Acanthamoeba* crude extract to adjust the two-phase composition to that of the solvent phases used for separation. The separation was carried out by pumping the PEG-rich

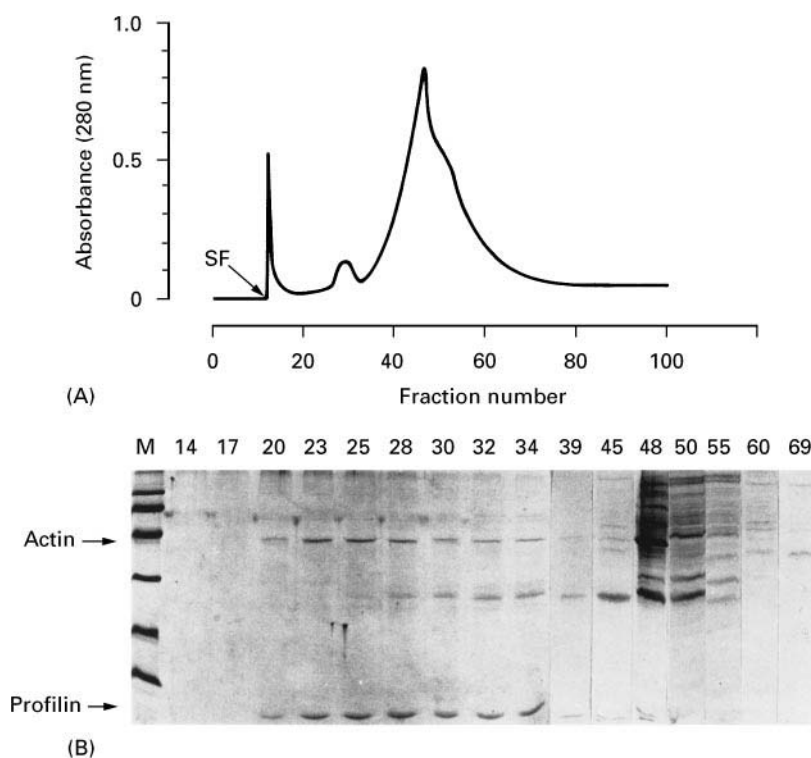

Figure 3 Purification of profilin-actin complex from *Acanthamoeba* soluble extract. Experimental conditions: column is a 2.6 mm i.d. PTFE multilayer coil $\times 2$, $\beta = 0.16$ – 0.27 ; 130 mL capacity; sample consists of 12.5 g *Acanthamoeba* soluble extract; solvent system is 4.4% (w/w) PEG 8000, 7% (w/w) dextran T500 in a 10 mmol L^{-1} potassium phosphate buffer at pH 6.8; mobile phase is the upper phase; flow rate: 0.5 mL min^{-1} ; revolution: 900 rpm; SF, solvent front.

upper phase into the head of the column at 0.5 mL min^{-1} under a high-revolution speed of 1000 rpm. The results are shown in Figure 3A. The solvent front emerged at the 14th fraction (3 mL per fraction) whereas the profilin-actin complex was eluted in fractions 20 to 28, well separated from other components. The impurities were mostly eluted later with a retention volume close to the total column capacity (around fractions 33–60), while some were also found near the solvent front (fraction 15). Identification of the profilin-actin complex was made by 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), as illustrated in Figure 3B. The retention of the lower stationary phase was 69% of the total column capacity.

Countercurrent Chromatographic Fractionation of Lipoproteins from Human Serum

The performance of the XLL cross-axis CPC has been evaluated by the direct separation of high- and low-density lipoproteins (HDLs and LDLs) from human serum. The effects of the molecular weight of the PEG was studied with a polymer-phase system composed

of 16% (w/w) PEG, 12.5% (w/w) potassium phosphate. Figure 4 shows the chromatograms of human serum (4 mL) obtained from four solvent systems containing different molecular weight PEGs (600, 1000, 2000 and 4000).

In each experiment, the CCC column was first entirely filled with the PEG-rich upper stationary phase, and the sample solution (a mixture of 4 mL human serum and 2 mL each of upper and lower phases, to which the required amounts of PEG and potassium phosphate were added to adjust the two-phase composition) was injected through the sample port. Then, the potassium phosphate-rich lower mobile phase was eluted through the column at a flow rate of 2 mL min^{-1} while the apparatus was rotated at 500 rpm. The lipoprotein fractions obtained in the CCC were characterized using polyacrylamide gel disc electrophoresis (disc PAGE). Serum proteins in the CCC fractions were also characterized by SDS-PAGE.

In the PEG 600 system (Figure 4A), all proteins including HDLs, LDLs and serum proteins were strongly retained in the PEG-rich stationary phase and eluted together when the column was eluted in

Figure 4 Countercurrent chromatographic fractionation of HDL-LDL and VLDL-serum protein fractions from human serum with four different aqueous polymer-phase systems containing (A) PEG 600; (B) PEG 1000; (C) PEG 2000; (D) PEG 4000. Experimental conditions: column is a 2.6 mm i.d. PTFE multilayer coil \times 2, $\beta = 0.76$ –0.90, 340 mL capacity; sample is a mixture of 4 mL volume of human serum, 2 mL of the upper and the lower phases, to which the required amounts of PEG and potassium phosphate were added to adjust the two-phase composition; solvent system consists of 16% (w/w) PEG 1000, 12.5% (w/w) K_2HPO_4 (pH 9.2); mobile phase is the lower phase; flow rate: 2.0 mL min^{-1} revolution: 500 rpm; SF, solvent front; UP, starting point of the reversed elution mode with the upper phase mobile.

a reversed elution mode with the PEG-rich upper phase. Similarly, when PEGs with molecular weights higher than 2000 were used in the solvent system, all proteins including HDLs, LDLs and serum proteins were mostly distributed to the potassium phosphate-rich lower phase and eluted together at the solvent front (Figure 4C and D). Successful separation of the combined HDL and LDL fraction was achieved with the 16% (w/w) PEG 1000, 12.5% (w/w) potassium phosphate solvent system at pH 9.2, where both HDLs and LDLs were eluted together near the solvent front, while other proteins, including very-low-density lipoproteins (VLDLs) and serum proteins were retained in the column for much longer. The separation time of these two lipoproteins was 3 h. The VLDLs were eluted by the PEG-rich upper phase in the second peak or its shoulder (Figure 4B).

These results show that both HDL-LDL and VLDL-serum protein fractions were fractionated within 3 h by CCC with a polymer-phase system composed of 16% (w/w) PEG 1000 and 12.5% (w/w) dibasic potassium phosphate at a relatively high flow rate of 2 mL min^{-1} .

Purification of HDLs, LDLs and VLDLs from Human Serum by Combined Use of CCC and Hydroxyapatite Chromatography

In the previous section, two lipoprotein fractions (HDL-LDL and VLDL-serum proteins) were obtained from human serum using a polymer-phase system by the type XL cross-axis CPC equipped with a large-capacity column (340 mL). A small-capacity column (60 mL) mounted on the same apparatus can be employed to shorten the separation time. Figure 5 shows a chromatogram of human serum (4 mL) obtained with the cross-axis CPC using 16% (w/w) PEG 1000, 12.5% (w/w) dibasic potassium phosphate (pH 9.2). The separation was performed at 500 rpm and at a flow rate of 0.5 mL min^{-1} using the lower phase as the mobile phase. Both HDLs and LDLs were eluted together near the solvent front, while other proteins were retained in the column much longer. After collecting the HDL-LDL fraction (CCC-fr. 1), VLDLs were eluted together with serum proteins (CCC-fr. 2) by pumping the upper phase in the reverse direction. The separation was completed within 4.5 h. The lipoproteins in each peak were confirmed by agarose gel electrophoresis with Oil Red 7B staining, and the serum proteins were also detected by 10% SDS-PAGE with Coomassie Brilliant Blue protein staining.

The CCC fractions 1 (HDL-LDL) and 2 (VLDL-serum proteins) were each separately dialysed against distilled water until the concentration of the potassium phosphate was reduced to that in the starting

Figure 5 Countercurrent chromatographic separation of HDL-LDL and VLDL-serum protein fractions from human serum by small-capacity columns. Experimental conditions: column is a 2.6 mm i.d. PTFE multilayer coil $\times 2$, $\beta = 0.76$, 60 mL capacity; sample is a 4 mL volume of human serum containing 0.9 g PEG 1000 and 0.7 g dibasic potassium phosphate; solvent system consists of 16% (w/w) PEG 1000, 12.5% (w/w) K_2HPO_4 (pH 9.2); mobile phase is the lower phase; flow rate: 0.5 mL min^{-1} ; revolution: 500 rpm; SF, solvent front; UP, starting point of the reversed elution mode with the upper phase mobile.

buffer used for hydroxyapatite chromatography. The concentrates of both fractions were chromatographed separately on the hydroxyapatite column. Figure 6 shows the elution profile on hydroxyapatite obtained from CCC-fr. 1. A 1.4 mL volume of the concentrate was loaded on the Bio-Gel HTP DNA-grade column ($5.0 \times 2.5 \text{ cm i.d.}$) and eluted at 1.0 mL min^{-1} with 75 and 290 mmol L^{-1} potassium phosphate buffer at pH 7.4. Two lipoprotein peaks were eluted: the first peak (HA-fr. 1) contained HDLs and the second peak (HA-fr. 2) contained LDLs.

The concentrate (1.5 mL) of CCC-fr. 2 was similarly chromatographed (Figure 7). The separation was performed with two-step elution with 290 and 650 mmol L^{-1} potassium phosphate buffers at pH 7.4. Most of the serum proteins, including albumin and globulins, were eluted with 290 mmol L^{-1} potassium phosphate buffer (HA-fr. 3) at pH 7.4. The VLDLs, on the other hand, were retained in the

Figure 6 Stepwise elution profile of HDLs and LDLs of the CCC fractions by hydroxyapatite chromatography. Experimental conditions: column is Bio-Gel HTP DNA-grade hydroxyapatite (5.0×2.5 cm i.d.); eluents are 75 and 290 mmol L⁻¹ potassium phosphate buffers at pH 7.4; flow rate: 1.0 mL min⁻¹ sample is the 1.4 mL concentrate of HDL-LDL CCC fraction containing 13.9 mg total proteins (CCC-fr. 1).

column for much longer and were eluted with 650 mmol L⁻¹ potassium phosphate buffer (HA-fr. 4). Lipoproteins in the hydroxyapatite chromatographic

fractions were confirmed by agarose gel electrophoresis. The results of agarose gel electrophoresis indicated that HDLs, LDLs and VLDLs were present

in HA-fr. 1, HA-fr. 2 and HA-fr. 4, respectively. From the results of SDS-PAGE of the hydroxyapatite fractions, HA-frs. 1, 2 and 4 are free from serum proteins and HA-fr. 3 contained only serum proteins.

Purification of Recombinant Enzymes from Crude *Escherichia coli* Lysate

The capability of the XLL cross-axis CPC was further examined in the purification of some recombinant enzymes from a crude extract of *Escherichia coli* lysate. The polymer-phase system used was 16%

(w/w) PEG 1000, 6.25% (w/w) monobasic and 6.25% (w/w) dibasic potassium phosphate (pH 6.8). The phosphate-rich lower phase was used as the stationary phase. About 1.0 mL of crude lysate containing purine nucleoside phosphorylase (PNP) in 10 mL of the above solvent system was loaded into the multilayer coil and eluted with the PEG-rich upper phase at a flow rate of 0.5 mL min^{-1} . **Figure 8A** shows the chromatogram of crude PNP lysate obtained. A 3 mL volume was collected in each fraction. The solvent front emerged at the 46th fraction (138 mL retention volume) and purified PNP was obtained from fractions 65–80 (195–240 mL). **Figure 8B** shows the 12% SDS gel electrophoresis patterns of the CCC fractions obtained from the crude PNP lysate. Gel electrophoresis clearly demonstrates that PNP in the crude *E. coli* lysate was highly purified by CCC via a single pass through the column.

Purification of recombinant uridine phosphorylase (UrdPase) from *E. coli* lysate has been performed similarly, as shown in **Figure 9**. The polymer phase system was the same as that used for the purification of recombinant PNP described above. About 2.0 mL of the crude lysate in 4 mL of the solvent, 1 mL of upper phase and 3 mL of lower phase containing 16% PEG 1000 and 12.5% potassium phosphate, was loaded on the column and eluted with the PEG-rich upper phase at 0.5 mL min^{-1} . In **Figure 9**, protein concentration in the eluted fractions (solid line) is plotted against the retention volume. The chromatogram shows four protein peaks. Most of the protein mass was eluted immediately after the solvent front in fractions 35–55 (105–165 mL), whereas the enzyme activity of the UrdPase coincides with the fourth protein peak corresponding to fractions 75–95 (230–285 mL). These results indicate that recombinant UrdPase can be highly purified from the crude *E. coli* lysate in a one-step operation within 10 h by the XLL cross-axis CPC.

Purification of Lactic Acid Dehydrogenase from Bovine Heart Crude Extract

CCC has been applied to the purification of lactic acid dehydrogenase (LDH) from a crude bovine heart filtrate using the XL cross-axis CPC. The separation was performed with a polymer-phase system, composed of 16% (w/w) PEG 1000, 12.5% (w/w) potassium phosphate at pH 7.3.

Figure 10A shows chromatograms of the bovine heart crude extract obtained, where the PEG-rich upper phase was used as the stationary phase. The separation was performed at 500 rpm at a flow rate of 1.0 mL min^{-1} using the phosphate-rich lower phase as the mobile phase. The enzymatic activity of LDH was detected between the second and third

Figure 9 Countercurrent chromatographic purification of uridine phosphorylase (UrdPase) from crude *Escherichia coli* lysate. Experimental conditions: column is a 2.6 mm i.d. PTFE multilayer coil $\times 2$, $\beta = 0.25$ – 0.60 , 250 mL capacity; sample consists of 2 mL crude UrdPase in 4 mL solvent; solvent system consists of 16% (w/w) PEG 1000, 6.25% (w/w) K_2HPO_4 and 6.25% (w/w) KH_2PO_4 (pH 6.8); mobile phase is the lower phase; flow rate: 0.5 mL min^{-1} ; revolution: 750 rpm; SF, solvent front.

peaks. These fractions were analysed by 12% (w/v) SDS-PAGE with Coomassie Brilliant Blue staining (Figure 10B), indicating that the LDH is actually contained in 30 mL of eluent (fractions 140–170 mL) without detectable contamination from other proteins. The traditional techniques used for purification of LDH require several steps, including precipitation with ammonium sulfate, centrifugation and dialysis;

hence they are very tedious and time-consuming. By combined use of the XL cross-axis CPC and the aqueous polymer-phase system described above, LDH is purified within 3 h.

These results show that, with relatively simple manipulation of several parameters (buffer, polymer molecular mass, rotation speed), CCC is well suited to the rapid purification of enzymes from very crude

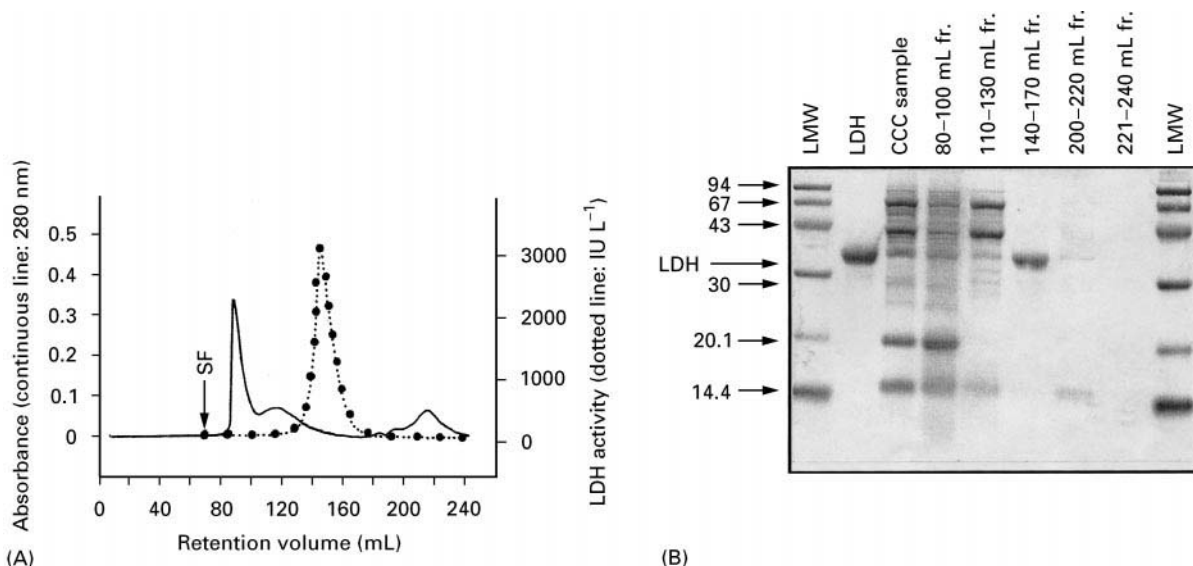

Figure 10 (See Colour Plate 116) (A) Countercurrent chromatography of bovine heart homogenate and (B) SDS-PAGE profile of the fractions. Experimental conditions: column is a 2.6 mm i.d. PTFE multilayer coil $\times 2$, $\beta = 0.50$ – 0.60 , 165 mL capacity; sample is a mixture of 3 mL bovine heart crude extract, 3 mL solvent system (1.5 mL each phase); solvent system consists of 16% (w/w) PEG 1000 12.5% (w/w) potassium phosphate (pH 7.3); mobile phase is the lower phase; flow rate: 2.0 mL min^{-1} ; revolution: 500 rpm; SF, solvent front. LMW, low molecular weight protein markers.

tissue extracts. Because of the protective effect of a high concentration of polymers and potassium phosphate, the native structure of the proteins is preserved at room temperature during separation, and the support-free partitioning eliminates sample loss and deactivation of enzymes which is often caused by using the solid support in conventional chromatography. We expect that these merits of the method will apply in the purification of other enzymes.

Conclusion

The capability of the cross-axis CPCs for performing CCC has been demonstrated in the separation and purification of proteins. The unique feature of the apparatus is that it provides sufficient retention of the stationary phase for viscous, low interfacial tension polar solvent systems, such as aqueous-aqueous polymer phase systems. Consequently, the method can be utilized for the fractionation of a wide variety of proteins without adsorptive sample loss and denaturation of proteins caused by the solid support. The CCC method may be further extended to the purification and fractionation of other biopolymers.

Introduction

Proteins are polymers of amino acids, the so-called 'building blocks of nature' and are found in all living matter be it of animal, microbial or vegetable origin. By their very structure proteins have an electrical charge and can therefore be fractionated by ion exchange processes. This paper briefly reviews the principles underlying protein purification by ion exchange and addresses some of the process issues associated with their purification.

Proteins

As living cells reproduce, genetic material is passed from parent cells to daughter cells in the form of DNA. DNA is a template coding for the various proteins required for the developing organism. As the organism grows, cells differentiate to form the various organs of the mature organism. Each cell has the capability to express every single protein of the organism, but in life only a small fraction of proteins are expressed. For example muscle cells produce actin and myosin to facilitate movement, the pancreas produces chymotrypsinogen and trypsinogen to facilitate digestion and lymphocytes are responsible for the expression of immunoglobulins which provide immunity from infection and disease.

Because of their functional and structural roles in nature, proteins have significant commercial potential in many areas including food and beverage, biological detergents, diagnostic enzymes, veterinary, agricultural and pharmaceutical applications. However, because of their diversity, the challenges of their purification are immense and their isolation from a particular tissue or organ, regardless of host, may be regarded as 'searching for a needle in a haystack'.

Protein Structure

Proteins are polymers of amino acids bonded together through amide linkages. There exist 20 common amino acids in nature ranging in molecular mass from 75 to just over 200 Da. Proteins range in molecular mass from around 10 000 up to > 1 000 000 Da, and consequently their amino acid sequence or primary sequence may be hundreds of residues in length. Of the 20 amino acids, several have positively or negatively charged side chains, while others have neutral side chains, which may have hydrophilic or hydrophobic properties. The primary sequence of a protein results in a zwitterion with the positively charged N terminus balancing the negatively charged C terminus. However, the charges of the side chains of the charged amino acids and the pK_a values of their functional groups give, at least in principle, an overall positive or negative charge at a given pH. However, proteins are not simple structures and certain sequences of amino acids fold to give secondary structures such as helices and pleated sheets. This secondary structure scrambles up to give a three-dimensional tertiary structure. Some proteins exist as an assembly of subunits giving a quaternary structure. Many proteins are glycosylated to aid with molecular recognition *in vivo* and this influences their shape and surface properties.

The net effect of the three-dimensional structure of proteins is that their theoretical charge or hydrophobicity based on a primary sequence bears little relation to the actual properties of the molecule in its native state. If, for example, all the charged groups are buried inside a pocket in the molecule, then its response to an ion exchanger may be quite weak. The three-dimensional structure of a protein is associated with function and for the purified protein to have intrinsic value, its three-dimensional structure should be retained. This presents practical difficulties in terms of purification, because a denatured protein may not readily, if at all, refold back to its native state. For mammalian systems, typical physiological conditions are pH 7.4 and 0.15 M NaCl and most proteins would be stable and active under these conditions. However, deviations in operating pH and, to

a lesser extent, ionic strength, may irreversibly denature the protein of interest, which can severely restrict the mode of purification available to the chromatographer.

Methods of Protein Purification

Prior to carrying out any practical studies, the protein chemist is provided with a range of chromatographic techniques, the use of which should enable effective purification to be achieved. Those techniques suitable for low pressure operation include those listed in Table 1. While all of these techniques are suitable for laboratory-scale use, those typically scaled-up include ion exchange, hydrophobic interaction, affinity and size exclusion. These techniques each exploit differing physicochemical properties of the protein molecules as manifest by their three-dimensional structure. Ion exchange chromatography and hydrophobic interaction chromatography rely on electrostatic interactions between a charged stationary phase and charged surfaces of the protein or hydrophobic interactions between a hydrophobic stationary phase and hydrophobic surfaces of the protein respectively. Affinity separations rely on a biospecific interaction, for example the interaction of an enzyme with its immobilized substrate or an immunoglobulin with its immobilized antigen. Size exclusion chromatography is a molecular sieving effected by the three-dimensional size and shape of the protein. One or more of these techniques should be suitable for protein purification with their choice influenced by the selectivity requirements of the process in terms of both the target and contaminants.

Ionic Properties of Proteins

For the reasons described above, all proteins will have ionic properties, and their three-dimensional structure imparts a subtle uniqueness to their ionic charge, which is available for exploitation by ion exchange chromatography during their purification. In a similar manner to small molecules, such as organic acids, which vary their charge with pH, as prescribed by their pK_a , proteins have an isoelectric point or pI . The

Table 1 Techniques available for low pressure chromatography of proteins

Affinity
Chiral

pI of a protein is the pH where it has a net charge of zero.

When the pH is greater than the pI , the protein will have a net negative charge and may bind to an anion exchanger, provided that the pH is less than the pK_a of the functional group. If the pH is less than the pI the protein will have a net positive charge and may bind to a cation exchanger, provided the pH is greater than the pK_a of the functional group. As a rough guide most proteins have a pI of less than 7, ranging typically from 4.5 to 6.5. The major exceptions are the immunoglobulins which typically have a pI of greater than 7.

Ion Exchange Chromatography of Proteins

Principles

On the basis of the physicochemical issues discussed above, it might appear that by following a few simple rules, centred around pH , an ion exchange separation can be designed. The first barrier to overcome is to find out the pI of the protein. Unless the protein is well characterized, this may not be documented, and although it can be readily determined by techniques such as isoelectric focusing, this presupposes that it can be obtained in a relatively pure state. A second barrier is the pH and ionic strength stability ranges of the protein. This can be determined readily by a parametric study, centred around a robust assay for the protein, typically linked to its biological function. A third, and often underestimated barrier, is the influence of the other contaminants within the feedstream and how they may impact on the efficiency of the ion exchange separation. For example, competitive adsorption of an unwanted contaminant to the adsorbent can significantly hamper the selectivity of the separation and the process economics. Other key considerations include the mobile phase composition as defined by the preceding chromatographic step and its impact on an ion exchange separation and the eluent composition and its impact on the subsequent downstream step.

Method Scouting

In the light of the issues highlighted above, the chromatographer can start to develop the ion exchange process. A broad strategy for ion exchange is represented in **Figure 1**. Intuitively, it would seem reasonable to expect ion exchange steps to be of the positive form, whereby the target is retained by the exchanger, and assuming elution volume is less than feedstock volume, has the potential to effect product concentration. Such an approach may be preferable if

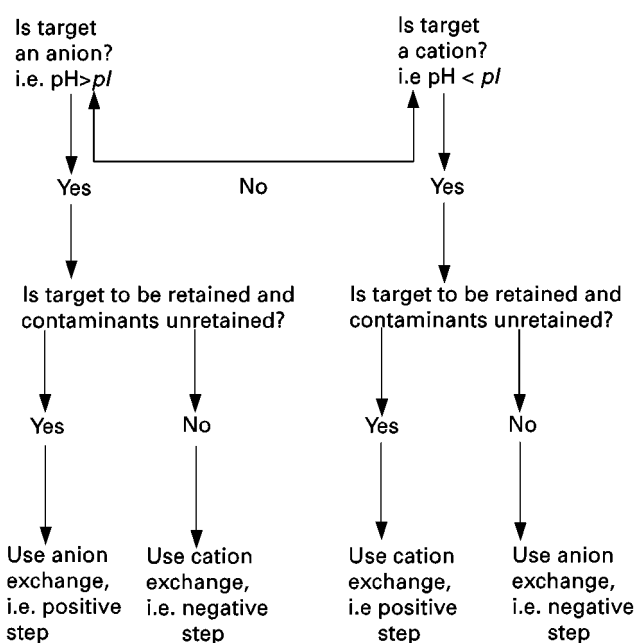

Figure 1 Approaches to development of an ion exchange chromatographic process. Copyright © 1998 Whatman International Ltd., reproduced with permission.

the target binds more strongly to the exchanger than the contaminants, so they are displaced by the target during loading. The isolation of ovalbumin from hen egg-white by anion exchange chromatography is one such example (**Figure 2**), where we have shown ovalbumin to displace the less anionic conalbumin component during adsorption. However, the desorbed protein product is typically in a mobile phase containing up to 1 M NaCl and this may be unsuitable for adsorption in a subsequent step, for example an affinity interaction. If this is the case then another unit process, such as diafiltration, needs to be introduced which may be costly, time-consuming and could result in additional yield/activity loss.

An approach which may often be dismissed, but in fact can be highly efficient is the negative step. In this case the contaminants bind to the adsorbent and the target passes unretained during loading. Since there is no volume reduction, product concentration remains constant, but purity increases. If the target is present in excess, then a modest adsorbent volume may suffice, which has an impact on cost, but perhaps as important, the mobile phase composition remains unchanged, which may facilitate the subsequent chromatographic step. Negative steps are routinely employed during immunoglobulin isolation from serum or plasma, where the anionic albumin contaminants adsorb to an anion exchanger at neutral pH , while the cationic immunoglobulin fraction passes unretained through the exchanger, as represented in **Figure 3**.

Figure 2 Chromatography of hen egg-white proteins on Whatman DE52 using 0.025 M Tris/HCl buffer, pH 7.5 in a column (45 cm i.d. \times 16 cm) at a flow rate of 1 L min⁻¹. Copyright © 1998 Whatman International Ltd., reproduced with permission.

These are some of the fundamental considerations during method scouting and are based on two questions. Firstly, at a given pH will the target bind to an anion exchanger or a cation exchanger? Secondly, is this what is wanted?

Figure 3 Chromatography of a goat serum preparation on Whatman QA52 using 0.02 M Tris/HCl buffer, pH 7.5 in a column (32.5 cm i.d. \times 12 cm). A, denotes a wash in loading buffer; B, denotes a wash using loading buffer containing 0.5 M NaCl. Copyright © 1998 Whatman International Ltd., reproduced with permission.

Given that the mobile phase of the feedstock is determined by the upstream process and any significant adjustments add cost and complexity, the chromatographer can now start to address these two questions. Due to the nature of proteins and the influences of protein : protein interactions which may occur in the feedstream, it is difficult, if not impossible, to predict the optimal chromatographic conditions without practical study. It is therefore common practice to carry out a parametric study, investigating the influence of pH and ionic strength with different ion exchangers. This is potentially a time-consuming process, but one that will aid in process optimization. This traditionally was performed manually, but more recently automated workstations have become commercially available which can be programmed to carry out multivariable parametric studies automatically.

Media Selection

A key consideration during method scouting is which ion exchanger to use. The protein chromatographer is offered a range of strong or weak anion or cation exchangers, from several suppliers. The functional groups are broadly similar across the range, but the base matrices range from polysaccharides including agarose, cellulose and dextran to polymeric supports and advanced composites. Given that each manufacturer has proprietary chemical processes, the offerings available are quite diverse. In order to assess the impact of media selection on method scouting and development, we screened 70 different commercially

available anion and cation exchangers, which may be considered for process-scale protein separations. Each medium was screened under identical conditions. Perhaps not surprisingly, our data demonstrated that 70 different media had 70 different properties. Our data, descriptive rather than prescriptive, suggest that media effectiveness is process dependent rather than supplier dependent and the thought process of 'it worked last time' is not an appropriate rationale for developing a second process using the same adsorbent.

Method Development

When an appropriate ion exchanger and mobile phase system have been identified, it must then be decided whether to conduct the separation in either a column contactor or a batch stirred tank system. The former technique, being contained, lends itself to automation and control, but the latter technique, albeit classical, should not be dismissed. If, for example, the feedstream/adsorbent volume ratio is high, perhaps $> 20:1$, then the time to pump the feedstream through a packed bed of adsorbent would be several hours. A batch stirred tank adsorption including medium collection by centrifugation should take less than 1 h. Similarly in a large scale process where several hundreds of kilograms of ion exchanger are used, columns are costly and often cumbersome to use, so a large batch system may be preferred due to its simplicity.

For highly selective separations where desorption and elution conditions are critical then a column-based technique would be appropriate, typically using gradient elution.

As stated earlier, proteins are large molecules with a size up to hundreds of angstroms and consequently diffusion into and out of the pores of an ion exchanger is the rate limiting step both in terms of capture efficiency during adsorption and selectivity during desorption and elution. In order to enhance each of these parameters, one needs to maximize residence time of the adsorbate with the adsorbent to increase the capture efficiency of the target protein and in order to maximize selectivity, one needs to provide adequate time for the desorbed protein to diffuse into the bulk liquid phase, so it elutes as a sharp peak. Flow rate is clearly the critical factor to regulate these adsorption/desorption rates and this equates with process-time. Unlike ion exchange of small ions, where pore diffusion rates while limiting have minimal criticality, they are crucial for effective ion exchange chromatography of proteins and must be considered during methods development. Typical linear flow rates for polysaccharide-based ion exchangers would be $30\text{--}300\text{ cm h}^{-1}$ and for advanced

polymeric-based media, a further 10-fold increase in flow may be possible. However, it should be noted that the maximum flow rate specification of the ion exchanger and an operational flow rate for effective protein binding and elution may be widely different, and will likely to be determined by the nature of the protein separation itself.

Scale-down Studies

Having defined the ion exchanger, the mobile phases and the mode of operation, a series of small scale studies will be carried out at the laboratory bench to assess process economics and perhaps to carry out sensitivity analysis and validation support studies.

Scaled-down studies are very valuable and enable a substantial amount of data to be generated and collated in a cost-effective manner, although the time-scale may be similar to that required for large scale work. The key feature of a small scale study is that the contactor is a scaled-down version of the process system. For a batch process the aspect ratio of the tank and tip speed of the agitator, etc., would be the same for both scales of operation. The ratio of feedstock volume to mass of ion exchanger would be constant as would the contact times for adsorption, washing and elution. For a column separation, column bed height would be identical at both scales of operation and linear flow rate would be maintained throughout the process. Provided that all mobile phase volumes used were in proportion to the amount of ion exchanger used, and that feedstock and buffer compositions remain unaltered, a small scale study should be a good model of the large scale process separation. In the anion exchange chromatography of hen egg-white proteins, for example, we have reported the 1000-fold scale-up of a column process from a 25 mL column to a 25 L column.

Process validation is a critical area in the isolation of therapeutic proteins. In these applications it is crucial that for multiple uses of the adsorbent, the eluting fraction containing the target protein has a consistent composition from run to run and that it meets a specification in terms of microbial bioburden, endotoxin levels, pyrogenicity and viral contamination. These aspects of process validation have been adequately reviewed by Sofer and Nystrom.

A widely used mobile phase for regeneration of ion exchangers following protein chromatography is sodium hydroxide. It is well established that exposure of a column of ion exchanger to $0.5\text{--}2.0\text{ M NaOH}$ for up to 12 h is an effective means of regenerating the medium. Importantly, these conditions are also acknowledged to be effective at sanitization of the ion exchange system, and we have confirmed this to be

the case following gross microbial contamination of columns of both anion and cation exchangers.

A key element of process validation is the chemical stability of the ion exchanger to the cleaning/sanitizing reagent systems. We have developed protocols for monitoring hydrolysis of functional groups, referred to as ligand leakage, and also matrix dissolution, in order to address these concerns.

These process validation studies are typically conducted in scale-down mode, and confirmatory checks made subsequently at process scale.

Process Scale Ion Exchange Chromatography of Proteins

Having defined the feedstock and mobile phases, selected the ion exchanger and selected a batch or column mode of operation, the chromatographer should find himself or herself in a position to scale-up the process.

It is difficult to predict cost information on process scale ion exchange separations since much depends on the upstream and downstream process requirements and reusability of the ion exchanger, etc. We have reported a cost estimate for single usage of 25 kg of DE52 in batch and column operation (see Ganetsos and Barker), but this is exemplary only. Unfortunately information of this type, while in existence, is proprietary and therefore withheld.

Industry has carried out large scale ion exchange chromatography of proteins for the last few decades

and with the established principles described above, there is no reason to assume that things will change significantly over the short to medium term. In the longer term, developments in fluidized/expanded beds and membrane adsorbers may offer new opportunities in this area of chromatography.

Introduction

The first complete genome sequence, that of *Haemophilus influenzae*, was published in 1995. Intense effort over the last three years has resulted in the completion of the genomes for a further 12 micro-organisms

ranging in complexity from *Mycoplasma genitalium*, with a genome size of only 0.58 Mb encoding less than 500 proteins, to *Escherichia coli*, with a genome size of 4.6 Mb encoding more than 4000 proteins (Table 1). The complexity of the eukaryotic genomes has resulted in slower progress, with only one organism, the yeast *Saccharomyces cerevisiae*, having been completed (Table 1). However, significant progress is being made for a variety of other species, with the estimated date for the completion of the human genome currently being 2001 (Table 1).

The vast amount of information being generated by the various genome sequencing programmes has the potential to contribute significantly to our understanding of how an organism functions and its evolutionary relationships with other life forms. However, it has already become clear that genomics alone will not provide all of the answers. For those organisms whose genomes have been completed, typically around 30% of the genes can be assigned definite functions with up to a further 30% being attributed functions on the basis of homology with other genes of known function. The remaining 40% of the structural genes can often not even be attributed putative

functions. A further limitation of the genomic approach is that it does not provide any insights into the ways an organism may modify its pattern of gene expression in response to different conditions.

Analysis of Gene Expression

These problems can only be solved by direct investigation of gene expression, which can be achieved at either the level of messenger RNA (mRNA) or protein. A variety of techniques such as cDNA microarrays and serial analysis of gene expression (SAGE) make it possible to undertake mass screening of mRNA expression and establish which particular mRNAs are expressed in an organism under any given condition. However, recent studies have highlighted an important limitation of this approach in that *there is not always a direct correlation between RNA abundance and the amount of the corresponding functional protein within the cell*.

A further major limitation of studies at the level of mRNA is that they are unable to provide any information of processes of co- and post-translational modification of proteins. The modification of proteins by processes such as phosphorylation, glycosylation, sulfation, hydroxylation, N-methylation, acylation, prenylation and N-myristoylation, can result in significant modulation of their functional properties. Knowledge of these processes is therefore important for a complete understanding of gene expression.

Table 1 Some organisms whose genomes have been completely sequenced and others which are the subject of active genome sequencing programmes

Organism	Size (Mb)	ORFs	Year completed

Proteome Analysis

The realization that these problems can only be addressed through studies at the level of protein expression has resulted in increasing interest in the area which has become known as 'proteome analysis'. The term 'proteome' was first coined by a collaborative team of scientists at Macquarie and Sydney Universities in 1995 and is defined as the **protein complement of the genome** of an organism. Increasing genomic complexity together with the potential for co- and post-translational modifications make proteome analysis a difficult task for higher organisms. As a consequence, active proteome programmes are currently restricted to some of the simpler organisms such as mollicutes (*M. genitalium*, *Spiroplasma melliferum*), prokaryotes (*E. coli*, *Chlamydia trachomatis*) and yeast (*S. cerevisiae*).

The complexity of eukaryotic proteomes has resulted in the term 'proteomics' or 'proteome analysis' being used in a narrower context in which it is used to characterize patterns of protein (and thereby gene) expression in particular cell type and tissues. This

approach can provide new insights into a variety of biological processes such as development, apoptosis and the cell cycle and add to our knowledge of the mechanisms that control gene expression. There is also considerable interest in applying proteomics to the study of diseases, where it promises further understanding of these processes at the molecular level and may lead to the discovery of new diagnostic markers and novel therapeutic targets. The pharmaceutical industry is also expressing considerable interest in the potential of proteomics in the process of drug discovery, as well as for analysis of the pharmaceutical and toxicological effects of existing therapeutics.

Need for Protein Separation

The five main steps of proteome analysis are shown in **Figure 1**. The primary requirement is that we must be able to separate the very complex protein mixtures present in lysates of cells, tissues and organisms. It is generally accepted that the best method currently available is two-dimensional polyacrylamide gel electrophoresis (2D electrophoresis). While there are several possibilities for combination of electrophoretic procedures, the most effective approach is a combination of a first-dimension separation by isoelectric focusing (IEF) under denaturing conditions with a second-dimension separation by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). This results in the sample proteins being separated according to their charge properties (i.e. isoelectric point, pI) in the first dimension followed

by a size-based (molecular weight) separation in the second dimension. As the charge and size properties of proteins are essentially independent parameters, this results in the sample proteins being distributed across the whole area of the 2D separation (**Figure 2**).

O'Farrell Method of 2D Electrophoresis

The method of 2D electrophoresis (2DE) described by O'Farrell in 1975 has formed the basis of almost all subsequent developments in 2-DE. This method used a combination of IEF in cylindrical gels (cast in capillary tubes) containing 8 M urea and 2% of the nonionic detergent, Nonidet P-40 (NP-40), with the SDS-PAGE system of Laemmli. However, for effective use in proteome analysis, 2DE must be capable of consistently reproducible high resolution protein separations. This proved to be problematic largely due to the nature of the synthetic carrier ampholytes (SCA) used to generate the pH gradients for IEF. SCA are small molecules which are freely mobile within the IEF gel, and the electroendosmotic flow of water which occurs during IEF results in their migration towards the cathode. This process is known as cathodic drift and results in pH gradient instability, with loss of the more basic proteins from the final 2D gel pattern.

2DE using IPG IEF

This problem has been largely overcome with the development of the Immobiline reagents (Amersham Pharmacia Biotech) for the generation of immobilized pH gradients (IPG) for IEF. The Immobiline reagents are acrylamide derivatives which give a series of buffers with different pK_a values distributed across the range pH 3–10. The appropriate Immobiline reagents, calculated from the extensive series of published recipes, are added to the mixture used for gel polymerization, resulting in the buffering groups which will form the pH gradient being covalently attached via vinyl bonds to the polyacrylamide backbone. This immobilization of the pH gradient renders it immune to the effects of electroendosmosis, resulting in highly stable IEF separations.

Despite early problems which were encountered in the application of IPG IEF to 2DE separations, this method has now become the method of choice for the first dimension of 2DE. The procedure which is now used is largely based on the work of Görg and her colleagues (see Further Reading). Briefly, IPG IEF is performed in individual gel strips, 3–5 mm wide, cast on plastic supports. After IEF, the gel strips are equilibrated to allow the separated proteins to interact with SDS, and then applied either to the

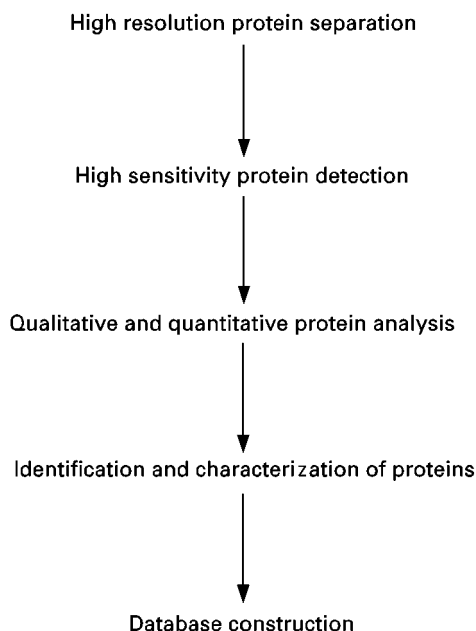

Figure 1 The five main steps in proteome analysis.

Figure 2 A 2DE separation of 100 μg of human heart using a nonlinear pH 3.5–10 IPG IEF gel was used in the first dimension and 12% SDS-PAGE in the second dimension. The separated proteins were visualized by silver staining.

surface of a horizontal SDS-PAGE gel to the top of a vertical. Interlaboratory studies of heart, barley and yeast proteins have unequivocally demonstrated the excellent reproducibility of both protein spot position and quantity that can be achieved with this method.

Separation Capacity of 2DE

The ability of 2DE to resolve complex mixtures of proteins is dependent on the gel area used for the separation. Thus, the 'standard' combination of 18 cm IPG strips with 20 cm SDS-PAGE gels is capable of routinely separating 2000 proteins from lysates of whole cells and tissues. It has been shown that very large gel formats (up to 30 cm in each dimension) are capable of separating up to 10 000 proteins from such samples, but this is achieved at the expense of the ease of gel handling and processing. In contrast, only a few hundred proteins can be separated using mini-format 2DE, but this approach has the advantage of rapid separations for screening purposes.

IPG IEF also provides great flexibility in the choice of pH gradient used for the separation, providing an additional approach to maximize the efficiency of separation of the particular protein mixture under investigation. Thus, IPG IEF gels spanning the range pH 3.5–10 are ideal for examining the diversity of protein

in a sample (Figure 2). Optimal resolution of proteins in a particular pH range can be achieved using narrower pH gradients (Figure 3).

A further advantage of IPG IEF is that it has a very high capacity for micropreparative 2DE protein separations, particularly using a recently described method in which IPG strips are reswollen directly in a solution containing up to several mg of the protein sample to be analysed.

Protein Detection

The next requirement for effective proteome analysis is detection of the separated proteins at high sensitivity. The Coomassie brilliant blue dyes have been the most commonly used reagents for detecting protein zones separated by gel electrophoresis, but their limited sensitivity (around 0.5 μg per protein spot) necessitates the use of relatively high sample loadings (> 500 μg). Much higher sensitivity of detection (0.1 ng per protein spot) can be achieved by silver staining (Figures 2 and 3), but there can be problems in using this method as a quantitative procedure as it is known to be non-stoichiometric. Silver staining intensity is linear over the range from 0.04 to 2 ng protein/ mm^2 , but above this limit the stain becomes nonlinear, resulting in saturation and even negative staining effects.

Figure 3 A 2DE separation of 100 μ g of human heart using a linear pH 4–7 IPG IEF gel was used in the first dimension and 12% SDS-PAGE in the second dimension. The separated proteins were visualized by silver staining.

Many of these problems can be overcome using detection methods based on the use of fluorescent compounds. Such methods are highly sensitive and generally exhibit excellent linearity and a high dynamic range, making it possible to achieve excellent quantitative analysis if a suitable imaging device is used. A variety of fluorescent compounds are available for labelling proteins prior to electrophoresis. However, such pre-electrophoretic staining often results in charge modification, resulting in alterations in spot positions during 2DE. Recently, compounds which react with cysteine or lysine residues have been used successfully for 2DE. The cysteine-reactive reagent, monobromobimane was found to have a sensitivity of 1 pg protein per spot when imaged using a cooled CCD camera. The amine-reactive cyanine dyes, propyl Cy3 and methyl Cy5, have been used to label *E. coli* proteins. These dyes are claimed to have an inherent positive charge, thereby preserving the overall charge of the proteins after coupling. Due to their spectral properties, the two dyes can be distinguished when present together, allowing two different samples each labelled with one of the dyes to be mixed together and separated on the same 2DE gel. This method, which has been termed difference gel electrophoresis (DIGE), has great potential for improving the efficiency of detection of differ-

ences in 2DE protein patterns between different samples.

One approach to overcoming the problems associated with charge modification during the IEF dimension is to label the proteins while present in the first dimension gel after IEF, prior to the second dimension separation by SDS-PAGE. The fluorescent compound 2-methoxy-2,4-diphenyl-3(2H)-furanone (MDPF) and a fluorescent maleimide derivative have been used in this way. The alternative approach is to label the proteins after the 2DE separation has been completed. Recently, two post-electrophoretic fluorescent staining reagents, SYPRO orange and red have been described. These stains have a very high sensitivity (2 ng protein per spot) and excellent linearity with a high dynamic range.

Metabolic labelling of proteins with a radiolabelled amino acid prior to their separation by 2DE provides a very sensitive method for protein detection. This approach is most commonly used with *in vitro* cell culture systems, but it is also possible to radiolabel synthetically the proteins in small pieces of fresh tissue. While proteins can be readily radiolabelled postsynthetically by methods such as radioiodination with [125 I] or reductive methylation with [3 H]-sodium borohydride, these result in significant charge modifications precluding their use in proteome analysis.

Qualitative and Quantitative Analysis

The first step in the analysis of 2DE protein profiles is to produce a digitized image. Stained gels can be digitized using a flat-bed scanning laser densitometer or a suitably modified document scanner. Autoradiographic film images of 2DE separations of radiolabelled proteins can also be imaged in this way, but more accurate quantitation can be achieved using a phosphorimaging scanner. Fluorescently labelled protein separation patterns can be visualized using either a dedicated scanning laser densitometer (fluorimeter) or a camera system fitted with cooled CCD array. Several commercial software systems for the analysis of 2DE gels are now available running on desktop workstations (Unix, PC, Mac). These systems make it possible to extract quantitative and qualitative information from individual 2DE gels, to match protein patterns from large collections of 2DE gels, and thereby establish comprehensive databases which can be used to investigate quantitative protein expression in cells, tissues and organisms.

Protein Identification and Characterization

It is clear from the foregoing that 2DE provides information on the *pI*, molecular weight and relative abundance of the separated proteins. However, it provides no direct clues to their identities or functions. The *pI* and molecular weight information can be used to search sequence databases for proteins with similar properties, for example using the TagIdent tool (<http://www.expasy.ch/www/guess->

[prot.html](http://www.expasy.ch/www/guess-prot.html)), but the uncertainty of molecular weight estimation by SDS-PAGE (typically around $\pm 10\%$) makes this process unreliable. Recently, mass spectrometry (MS) has been used to measure directly the mass of proteins separated by 2DE. In this approach the proteins are transferred by Western blotting onto the surface of a nitrocellulose or PVDF membrane which is then treated with a matrix required for MS. The protein spot of interest is excised, mounted directly into a matrix-associated laser desorption/ionization mass spectrometer (MALDI-MS) and the mass of the intact protein measured (Figure 4). We have found that this method is very accurate, usually within 1% of the predicted mass, but requires a MALDI-MS fitted with an infrared laser. While such mass data can be invaluable in characterizing post-translational modifications of proteins, it is unlikely on its own to result in unequivocal protein identification. Fortunately, over the last few years, several methods have been developed which make it possible to identify and characterize proteins separated by 2DE (Figure 5).

Western Blotting

The first major advance in the characterization of proteins separated by gel electrophoresis was the development of Western blotting. In this technique, the separated proteins are transferred ('blotted') from the restrictive gel matrix, usually by application of an electric field perpendicular to the plane of the gel ('electroblotting'), onto the surface of a suitable membrane support such as nitrocellulose or PVDF. The proteins can then be probed with a variety of ligands,

Figure 4 IR-MALDI mass spectrum of a protein spot from a 2D gel electroblotted onto a PVDF membrane. Mass peaks indicated are multiply charged or dimers of the molecular ion. The protein spot is known to be cardiac α -actin. The measured mass of the molecular ion (41842.1) is very close to the theoretical value determined from its amino acid sequence (41784.6).

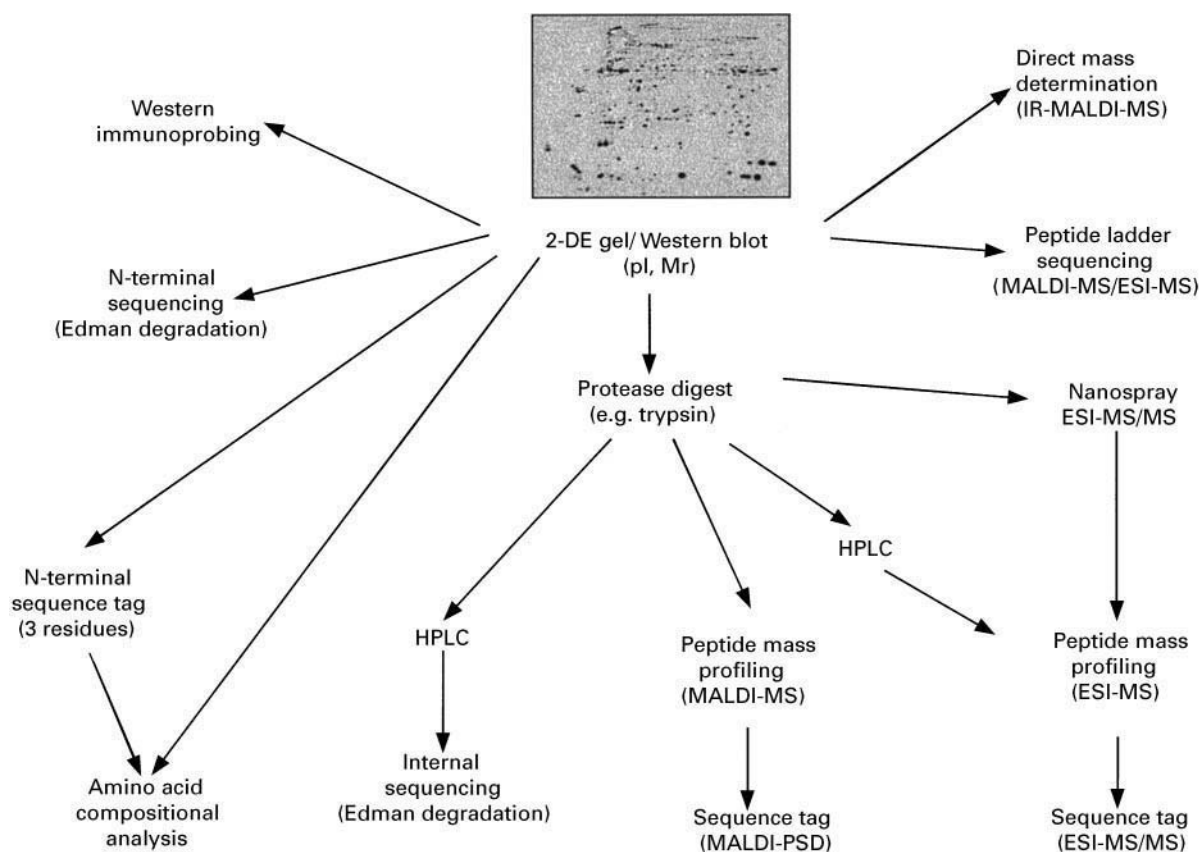

Figure 5 Methods currently used for the identification and characterization of proteins separated by 2DE.

particularly poly- and monoclonal antibodies. This approach has been used quite extensively for the identification of known proteins separated by 2DE, but is a very time-consuming process that is dependent on the availability of a suitable panel of specific antibodies reactive with the denatured proteins in 2DE gels.

Amino Acid Sequence Determination by Edman Degradation

Amino acid sequence, even if this is only a few residues in length, is the most specific method of protein identification. The chemical sequencing of proteins has been possible for half a century since the development of the method known as Edman degradation in 1949. This remained a laborious manual procedure until the development of the first automated protein sequenators, with the first commercial 'spinning cup' instrument becoming available in 1971. This instrument was relatively insensitive, requiring at least 10 nmol of sample (equivalent to 500 µg for a 50 kDa protein). However, progress in sequenator technology has resulted in the current generation of gas-liquid sequenators which are capable of generat-

ing N-terminal sequence information from low picomole quantities of protein (1 pmol is equivalent to 0.05 µg for a 50 kDa protein). This level of sensitivity is compatible with the amount represented by many of the spots present on micropreparative 2DE gels and this method remains the method of choice if extended runs of N-terminal protein sequence are required. This is a particularly important consideration for the analysis of apparently 'novel' proteins, i.e. sequences not present in protein and nucleotide databases. Although chemical protein sequencing is a sensitive and informative method of protein identification, throughput is very low, typically one or two samples per day. Thus, there is a need for alternative approaches which allow rapid and sensitive screening of gel proteins separated by 2DE, so that only those which cannot be identified unequivocally or appear to be novel require further detailed characterization.

Problem of N-Terminal Blockage

A major problem with protein sequencing by Edman degradation is that many proteins lack a free α -amino group, due to co- or post-translational modification.

Such N-terminal blockage occurs typically in up to 50% of eukaryotic proteins and results in no sequence being obtained. This problem can be overcome by subjecting the separated protein, either *in situ* within the gel matrix or after Western blot transfer onto a nitrocellulose or PVDF membrane, to chemical (e.g. CNBr) or enzymatic (e.g. trypsin) cleavage to generate shorter peptides which can be isolated and sequenced. The cleavage products are then usually separated by RP-HPLC, and selected peptide fractions directly applied to the protein sequenator. This procedure is highly efficient, but the determination of multiple stretches of sequence usually requires two to three times more protein than does N-terminal protein sequence analysis.

Amino Acid Compositional Analysis

Amino acid compositional analysis (AAA) is the best method for the absolute measurement of protein abundance. Current methods for the analysis of fluorescently derivatized amino acids have sub-pmole sensitivity and so can be applied directly to proteins separated by 2DE. An individual proteins have more or less unique amino acid compositions, AAA can be an excellent method for the rapid identification of proteins separated by 2DE, in which the experimental amino acid composition is compared with amino acid sequences generated *in silico* from protein and nucleotide sequence databases. The major drawback of this approach is that the output is a ranked list of possible protein identities (Figure 6) and the 'correct' protein does not necessarily occur as the first ranked entry. This method is better used in conjunction with another rapid method of protein identification such as peptide mass profiling (see later) and this orthogonal approach has been found to be useful for identifying proteins even across the species barrier. Another approach to improving protein identification by AAA is to generate a short N-terminal protein 'sequence tag' by Edman degradation and to use this in combination with the AAA data for protein identification.

Peptide Mass Profiling

It has long been realized that the peptides generated by chemical (e.g. CNBr) or enzymic (e.g. trypsin) digestion of a protein are characteristic of that protein and such peptide fingerprints or maps analysed by chromatography or electrophoresis have been used for investigating the relatedness of proteins. The advent of MS methods for the analysis of peptides has made this into a much more powerful approach for protein identification. In this method the peptide

masses obtained by MS of a protein digest are used to interrogate databases of peptide masses generated *in silico* from protein and nucleotide sequence databases. As in the case of AAA, this technique of peptide mass profiling or fingerprinting produces a list of possible protein identities ranked in order of probability (Figure 7). The reliability of this method can be increased by combining peptide mass profiling data from two or more separate digests (e.g. trypsin, Lys-C) or by adopting an orthogonal approach in combination with AAA (see above).

The enzymatic cleavage of the 2DE protein spot can be carried out either *in situ* within the gel matrix or after electroblotting to a suitable membrane (nitrocellulose or PVDF). After recovery, the unfractionated peptide can be readily analysed by MALDI-MS (Figure 7). Alternatively, the peptide mixture can be fractionated by high performance liquid chromatography (HPLC), with the fractions being analysed either offline by MALDI-MS or online by electrospray ionization (ESI)-MS using a quadrupole or ion-trap instrument.

Amino Acid Sequence Determination by Mass Spectrometry

Recently alternative techniques for the determination of the primary sequence of peptides and proteins have been developed based on the use of mass spectrometry (MS). This can be achieved by peptide fragmentation within the spectrometer or by a method termed 'ladder sequencing'. In the latter approach, Edman chemistry or enzymic degradation with aminopeptidase or carboxypeptidase is used under limiting conditions to produce an overlapping series of truncated peptides. These differ in size according to the number of amino acid residues which have been removed from their N- or C-terminus, allowing the sequence to be deduced by measurement of the peptide masses by MALDI-MS. A high mass accuracy is required and it is not possible to distinguish between leucine and isoleucine as these residues have an identical mass.

The alternative approach is to take advantage of the ability of two-stage mass spectrometers, either MALDI-MS with post-source decay (PSD) or ESI-MS/MS triple-quadrupole or ion-trap instruments, to induce fragmentation of peptide bonds. It is possible to use this approach to generate extended *de novo* amino acid sequence information, but it requires considerable expertise to interpret the complex spectra that are obtained. However, partial sequence data is an extremely powerful adjunct to the identification of proteins by peptide mass profiling.

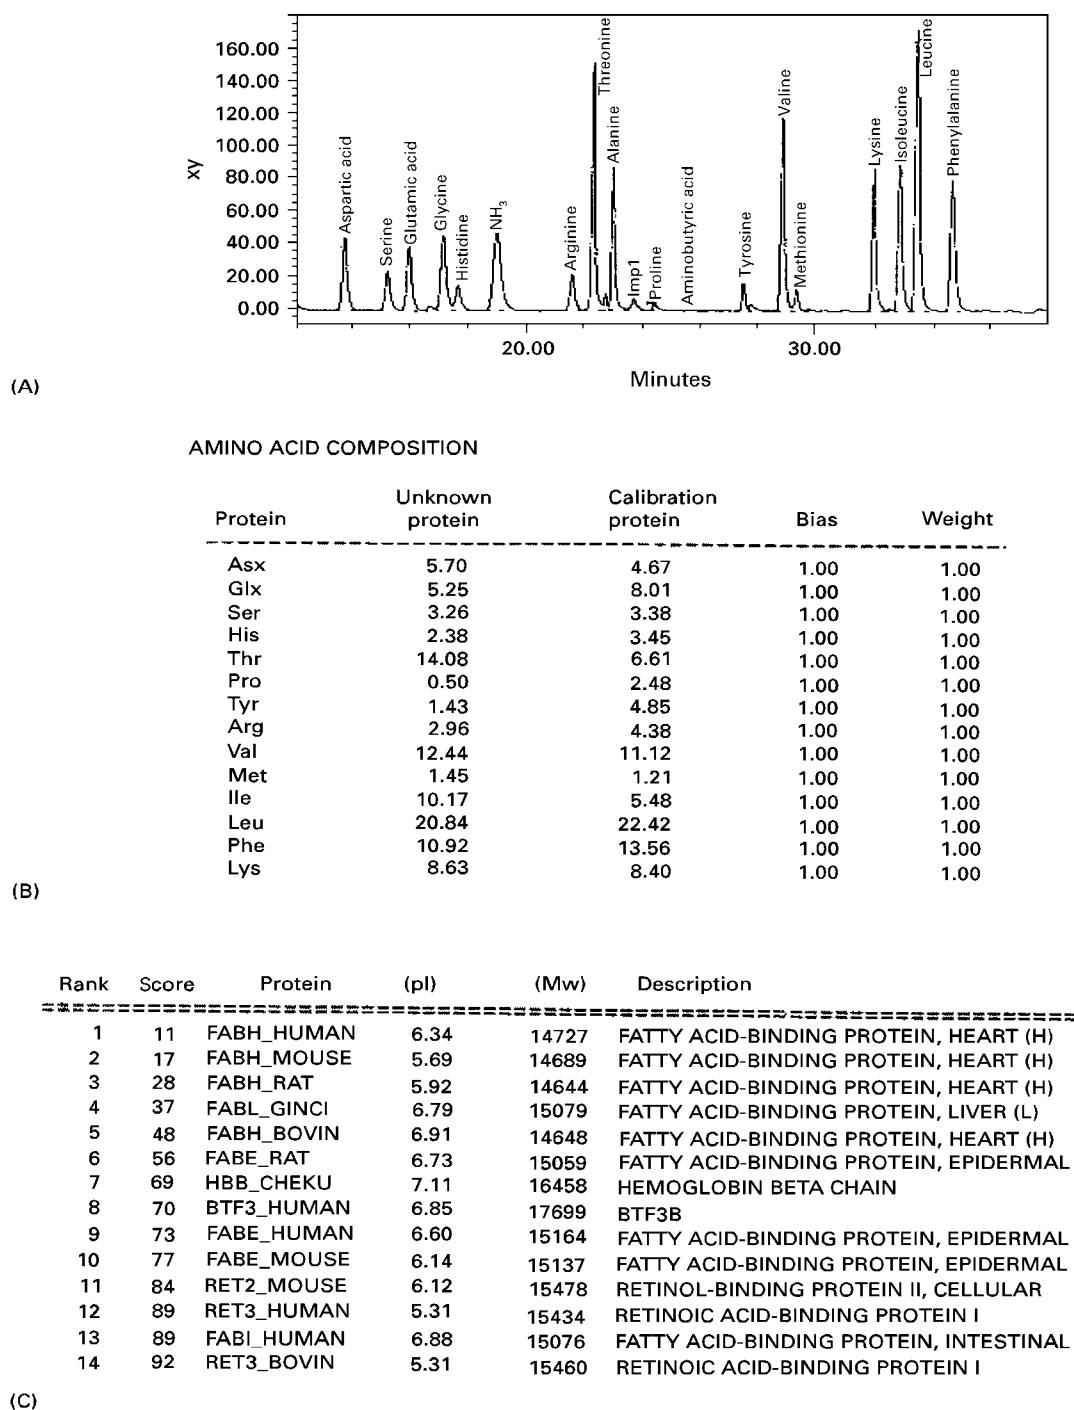

Figure 6 The identification of a protein spot from a 2DE separation by amino acid compositional analysis. (A) HPLC analysis of pre-column derivatized amino acids resulting from hydrolysis of the protein spot. (B) Amino acid composition determined from the HPLC analysis. (C) Result of the amino acid composition database search indicating that the protein is cardiac fatty acid binding protein.

The method known as 'peptide sequences tagging' is based on interpretation of a portion of the ESI-MS/MS or PSD-MALDI-MS fragmentation data to generate a short partial sequence or 'tag', which is used in combination with the mass of the intact parent peptide ion, and provides a significant amount of additional information for the homology search.

A powerful extension of this approach has been the development of a nano-electrospray ion source that allows spraying times of more than 30 min from about 1 μ L of sample. The sensitivity of this method is in the low femtomole range and silver stained 2DE protein spots containing as little as 5 ng protein have been successfully sequenced. Moreover, using this

Figure 7 The identification of a protein spot from a 2DE separation by peptide mass fingerprinting. (A) MALDI-MS spectrum of the tryptic digest of the protein spot. (B) Result of the peptide mass database search indicating that the protein is the M-chain of creatine kinase.

method it is possible to sequence multiple peptides from a digest without the need for their prior separation by RP-HPLC.

An alternative approach is based on the automated interpretation of ESI-MS/MS fragmentation data which is used to directly search sequence databases. In the first step in this process all those peptides that

can be generated from proteins in the sequence databases and whose masses match those of the measured peptide ion are identified. The fragment ions expected for each of the candidate peptides are then calculated and the experimentally determined MS/MS spectrum is then compared with the predicted spectra using cluster analysis algorithms. This

method has been fully automated and sensitivity is at the low femtomole level.

Database Construction

The final requirement for proteome analysis is the construction of databases to store the data generated and to make this readily available within the laboratory and, where possible, accessible to other scientists worldwide. The best approach to this is currently offered by the World Wide Web (WWW) on the Internet. There is currently no international standard for the construction of such databases, but in order that there should be good connectivity between them it has been suggested that they are constructed according to a set of fundamental rules. Databases conforming to these rules are said to be 'Federated 2D Databases' and a list of these can be viewed at WORLD-2DPAGE (<http://www.expasy.ch/ch2d/2d-index.html>).

Conclusions

From the foregoing discussion it can be seen that proteomics provides an interface with genomics which can provide information on protein expression in biological systems. This information will aid our understanding of complex cellular processes and the way in which they react to varying conditions. Proteomics will also provide insights into processes of disease at the molecular level and should result in the development of novel diagnostics and therapeutics.

QUANTITATIVE STRUCTURE-RETENTION RELATIONSHIPS (QSRR) IN CHROMATOGRAPHY

R. Kaliszan, Medical University of Gdańsk,
Gdańsk, Poland

Copyright © 2000 Academic Press

Introduction

To relate structure and chromatographic retention an approach is needed that lacks the rigour of thermodynamics but which provides otherwise inaccessible information. Such an approach is a combination of detailed models with certain thermodynamic concepts.

Linear free-energy relationships (LFER) may be regarded as linear relationships between the logarithms of the rate or equilibria constants for one reaction series and those for a second reaction series subjected to the same variation in reactant structure or reaction conditions. Retention parameters can be assumed to reflect the free-energy changes associated with the chromatographic distribution process. Accordingly, a chromatographic column can be treated as a 'free-energy transducer', translating differences in chemical potentials of analytes, arising from differences in their structure, into quantitative differences in retention parameters.

Assuming LFER it is possible to determine relative inputs of individual structural groups, fragments or features, to a property measured for a series of compounds in various chemical, physical, physicochemical and biological experiments. Such structural parameters (descriptors) can then be related to retention parameters.

The existence of LFER is normally proved statistically. The basic methodology of employing LFER to predict differences in pharmacological activity within a series of related agents was proposed in 1964 by Hansch and Fujita (QSAR, quantitative structure-activity relationships). Multiple regression analysis was applied in 1977 to chromatographic data (QSRR, quantitative structure-retention relationships). Other chemometric methods of data analysis have since been introduced to QSRR. QSRR are now one of the most extensively studied manifestations of LFER and, at the same time, the most common application of chemometrics.

Methodology and Goals of QSRR Analysis

To undertake QSRR studies two kinds of input data are needed (Figure 1). One is a set of quantitatively comparable retention data (dependent variable) for a sufficiently large (for statistical reason) set of analytes. The other is a set of quantities (independent variables) assumed to account for structural differences among the analytes being studied. Through the use of chemometric computational techniques, retention parameters are characterized in terms of various descriptors of analytes (and/or their combinations) or in terms of systematic knowledge extracted (learnt) from these descriptors.

To obtain statistically significant and physically meaningful QSRR, reliable input data are required and stringent mathematical analysis must be carried out. If this is not done, formally valid correlations may be developed for chemically invalid principles.

Once good QSRR have been obtained, one can exploit them for:

1. prediction of retention of a new analyte;
2. identification of the most informative structural descriptors possessing the highest retention prediction potency;
3. insight into the molecular mechanism of separation operating in individual chromatographic systems;
4. evaluation of physicochemical properties of analytes, e.g. their hydrophobicity (lipophilicity);
5. prediction of relative biological (pharmacological) activities within a set of drugs and other xenobiotics.

Retention Parameters for QSRR

The great advantage of the QSRR analysis over other quantitative structure-property relationship studies is that chromatography can readily produce a large amount of relatively precise and reproducible data. In a chromatographic process all conditions may be kept constant and hence the structure of an analyte becomes the single independent variable in the system.

The most commonly used retention parameter in gas chromatography is the Kováts retention index. When the adjusted retention times are used to calculate retention indices, parameters are obtained that

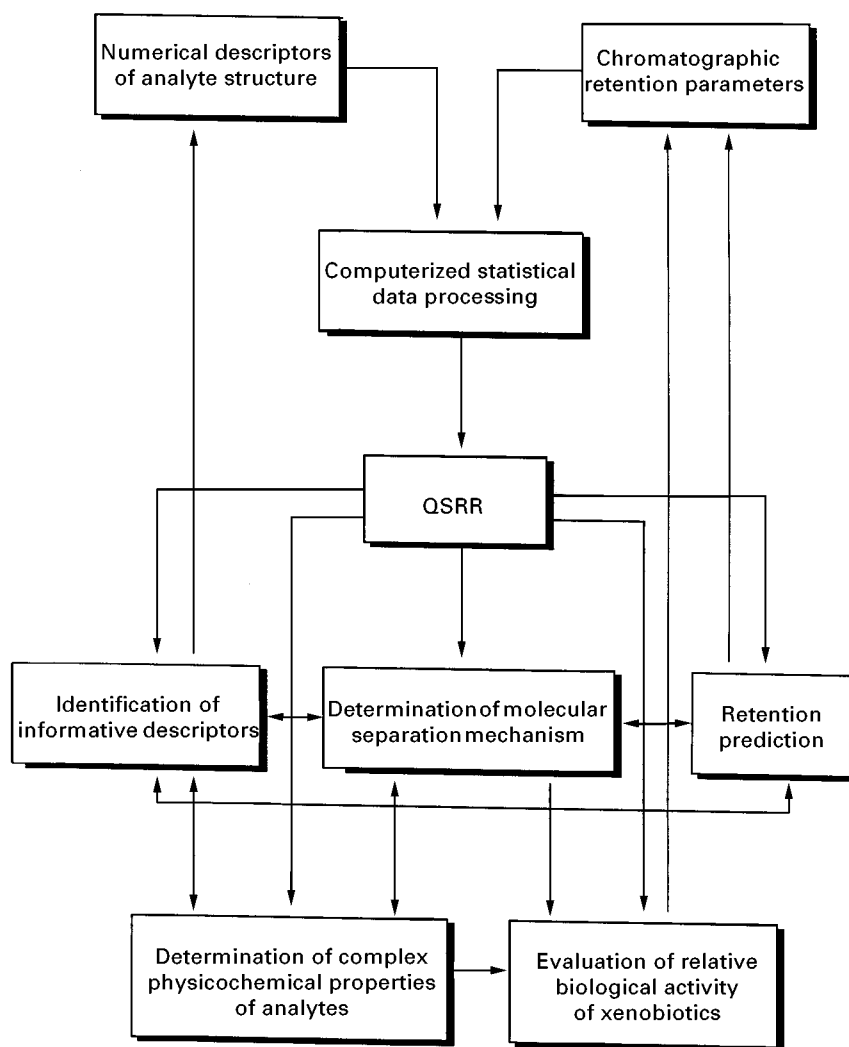

Figure 1 Methodology and goals of studies of quantitative structure-retention relationships (QSRR). (Adapted with permission from Kaliszan R (1992) Quantitative structure-retention relationships. *Analytical Chemistry* 64: 619A-631A. Copyright 1992 American Chemical Society.)

depend only on the column temperature and the stationary phase used. Kováts retention indices are highly reproducible; with a well-designed experimental technique, an interlaboratory reproducibility of one unit is possible. Sometimes in QSRR studies the logarithms of retention volumes of solutes are used instead of Kováts indices.

Classical thin-layer chromatographic (TLC) retention parameters are of rather limited reproducibility. The use of well-defined small-diameter stationary phase particles and a better knowledge of the parameters that determine the efficiency of chromatographic systems have led to the development of high performance TLC (HPTLC). An advantage of TLC over column chromatography, from the point of view of QSRR studies, is that tens of analytes can be simultaneously chromatographed on the same plate.

The retention parameter from TLC (and also from paper chromatography) that is normally used in QSRR is the R_M value. The R_M value is defined as $\log((1/R_F) - 1)$, where R_F is the distance migrated by the sample from the origin compared with the distance migrated by the solvent front from the origin.

The LFER-based retention parameter in high performance liquid chromatography (HPLC) is the logarithm of the retention factor k . The retention factor is defined as in eqn [1].

$$k = (t_R - t_M)/t_M = (V_R - V_M)/V_M \quad [1]$$

where t_R and V_R are the retention time and the retention volume of the analyte. The quantities t_M and V_M denote the elution time and the elution volume of an unretained compound.

HPLC retention data for QSRR analysis are usually obtained by measuring $\log k$ at several fixed eluent compositions (isocratic conditions) and then by extrapolating the dependence of $\log k$ on a binary eluent composition to a common mobile phase composition based on the Soczewiński-Snyder model:

$$\log k = \log k_w - S\varphi \quad [2]$$

In eqn [2] S is a constant for a given analyte and a given HPLC system and φ is the volume fraction of one of the mobile phase components. In the case of reversed-phase HPLC, k_w is a hypothetical retention factor expected for pure water (buffer) mobile phase ($\varphi = 0$).

The curvature often observed in plots of $\log k$ versus φ leads to a quadratic relationship:

$$\ln k = A\varphi^2 + B\varphi + C \quad [3]$$

where A , B and C are constants for a given analyte and a given chromatographic system. The $\ln k$ value calculated from eqn [3] by assuming $\varphi = 0$ is only occasionally used in QSRR analysis.

In spite of considerable effort, the relationships between retention and mobile phase composition are approximate. Often the values of $\log k_w$ extrapolated from a number of isocratic measurements in water/organic modifier eluents of varying compositions to a pure water eluent (the intercepts in eqn [2]) are different from those determined experimentally (when this is possible). Reversed-phase HPLC $\log k_w$ data are also usually different when derived from aqueous systems modified with different organic solvents. Still, the determination of $\log k_w$ appears to be the most reliable means of normalizing the retention parameters for QSRR analysis.

It should be noted here that some workers advocate using as the dependent variable the parameter S from eqn [2] or its ratio to $\log k_w$.

The electrophoretic mobility, μ_{el} , of spherical particles is described by a simple equation:

$$\mu_{el} = (z\Phi)/(6\pi\eta aN) \quad [4]$$

where z is the effective charge, Φ is the charge per mole of protons, η is the viscosity of the medium, a is the radius of the charged species and N is the Avogadro number.

A parameter normally measured in capillary electrophoresis (CE) is migration time, t . In a given CE system this parameter is inversely proportional to the electrophoretic mobility, μ . A normalized parameter, μ ($\text{cm}^3 \text{V}^{-1}$) allows comparison of data obtained in different CE systems. If a series of analytes is analysed

under the same conditions, then $1/t$ and μ are equivalent.

Chemometric Procedures in QSRR

Assuming LFER, a given chromatographic retention parameter may be described (statistically) by a set of analyte structural descriptors:

$$\text{Retention parameter} = f(a_1x_1, \dots, a_nx_n) \quad [5]$$

The coefficients a_1 – a_n for individual n descriptors are calculated by multiple regression. There are computer programs available commercially that are able to derive regression coefficients and to evaluate a statistical value of the regression model assumed.

Whether or not any of the possible models are statistically significant is judged on the basis of several statistical significance parameters. Among them are: the correlation coefficient (R); the standard error of estimate (S_E); the value of the F-test of the overall significance (F); the values of t -test of significance of individual regressors (t); and the cross-correlation coefficients between the independent variables in the regression QSRR equation. Even if the values of these statistical parameters are within the acceptable range, one cannot exclude a chance correlation. This may result when too many variables are surveyed to correlate too few retention data.

Multivariate methods of data analysis, like discriminant analysis, factor analysis and principle component analysis, are often employed in chemometrics if multiple regression methods fail. The most popular chemometric method in QSRR is principle component analysis (PCA). By PCA one reduces the number of variables in a data set by finding linear combinations of those variables that explain most of the variability.

Commercially available software packages tabulate the component weights and the values of individual principal components. Plots of component weights for each variable (structural descriptor) are useful in QSRR analysis. Analogously, scatterplots for the first two principal components illustrate the distribution of objects (analytes) according to their inputs to the principal components.

There is an approach in QSRR in which principal components extracted from analysis of a large table of structural descriptors of analytes are regressed against the retention data in a multiple regression, i.e. principal component regression (PCR). The partial least squares (PLS) approach with cross-validation also finds application in QSRR.

Neural networks (NN) is a method of data analysis that emulates the brain's way of working. NNs are considered powerful tools and techniques for carrying out signal processing, modelling, forecasting and pattern recognition. A NN has its input neurons that load the system with descriptor values. Next, there are the hidden layers that weight and mix the incoming signals, and an output layer with neurons predicting the calibrated response values. The advantage of NNs lies in nonlinear transformations of signals occurring at every neuron. The NNs are trained to respond properly using a representative set of structural data and the corresponding retention parameters. The well-trained (but not an overtrained) NN predicts retention based on input information of an analyte.

Selection of Structural Descriptors

The translation of molecular structures into numerical descriptors is important not only in QSRR but also to many subdisciplines of chemistry and pharmacology.

A popular strategy for identifying structural parameters in QSRR analysis is to start from the accepted theories of chromatographic separation. Such structural parameters should quantify the abilities of analytes to take part in the postulated intermolecular interactions that determine chromatographic separations. Empirical or semiempirical structural parameters of analytes based on the solvatochromic comparison method and on linear solvation energy relationships (LSER) belong to that category of structural descriptors. Also, reliable predictions of retention have been demonstrated using the LFER-based experimental substituent or fragmental constants.

The structural descriptors that are commonly used in QSRR analysis are classified in **Table 1**.

The structural descriptors related to molecular size may be related to the ability of an analyte to take part in nonspecific intermolecular interactions (dispersive interactions or London interactions) with the components of a chromatographic system. They are the factors most often found significant in QSRR analysis. The bulkiness parameters are decisive in the description of separations of closely congeneric analytes. For example, carbon number normally suffices to differentiate the members of a homologous series. On the other hand, when dealing with the set of analytes of the same size (e.g. isomers), they may appear not to be significant in QSRR analysis. This does not mean that dispersive interactions are meaningless for separation of congeners but just that they are closely similar, and hence the respective term in

Table 1 Structural descriptors in QSRR

<i>Classification</i>	<i>Descriptors</i>
Molecular bulkiness descriptors	Carbon number Molecular mass Refractivity Polarizability Van der Waals volume and area Solvent-accessible volume and area Total energy
Molecular geometry descriptors	Length-to-breadth ratio Moments of inertia Shadow area parameters
Physicochemical empirical and semiempirical parameters	Hammett constants Hansch constants Taft steric constants Hydrophobic fragmental parameters Solubility parameters Linear solvation energy relationship (LSER) parameters Partition coefficients Boiling temperatures p <i>K</i> _a values
Molecular polarity descriptors	Dipole moments Atomic and fragmental electron excess charges Orbital energies of HOMO and LUMO Partially charged areas Local dipoles Submolecular polarity parameters
Molecular topological descriptors	Molecular connectivity indices Kappa indices Information content indices Topological electronic index
Indicator variables	Zero-one indices
<i>Ad hoc</i> designed descriptors	

the QSRR equation apparently loses statistical significance.

What is more or less intuitively understood as molecular polarity of an analyte is difficult to quantify unequivocally. The descriptors of polarity are expected to account for differences among analytes regarding their dipole-dipole, dipole-induced dipole, hydrogen bonding and electron pair donor-electron pair acceptor (EPD-EPA) interactions. To find a good descriptor of these chemically specific interactions is difficult; the more so since changes in the polarity of an analyte also change its ability to take part in size-related interactions and affect analyte geometry.

Obviously, geometry-related or molecular shape parameters are difficult to quantify one-dimensionally. Single numbers reflecting molecular shape

differences are adequate only in the case of rigid and planar solutes. They become significant in QSRR equations if the range of analytes considered comprises compounds of similar size and polarity.

Physical meaning of the molecular graph-derived descriptors is never clear *a priori*. It is rather that good QSRR allow for assigning physical meaning to individual topological indices.

The empirical physicochemical parameters have good informative value for determining the mechanism of retention operating in a given chromatographic system. The problem is, however, the lack of such descriptors for the analytes of interest in actual QSRR studies.

Indicator values ('dummy variables') 0–1 are assigned depending on the presence or absence of a given structural feature in an analyte molecule. They serve to improve statistics but help occasionally to identify a structural descriptor of real physical significance.

The established structural descriptors listed in Table 1 seldom suffice to derive QSRR for the actual chromatographic data and often *ad hoc* descriptors have to be designed and included. QSRR analysis helps to test the predictive potency of the proposed structural descriptors, which may also appear suitable for deriving other kinds of structure–property relationships.

Prediction of Retention

Prediction of retention within homologous series is feasible owing to the linear relationships that are normally observed between retention parameters, $\log k$, and carbon numbers of analytes, n (Figure 2). The slopes of lines, B , for various homologous series chromatographed under the same conditions are very similar, whereas the intercepts, A , may vary:

$$\log k = A + Bn \quad [6]$$

Occasionally linear correlations are observed between retention parameters and molecular bulkiness descriptors of analytes that are not homologues. A good prediction of retention within a series of related nonpolar analytes, such as polyaromatic hydrocarbons (PAH) or alkylbenzenes, can be obtained using van der Waals volume as the structural descriptor.

The bulkiness descriptors can account for separation of analytes when dispersive interactions (London interactions) are the only interactions effective in a given chromatographic system, or when differences in polar interactions among analytes are not significant.

Figure 2 Plots of $\log k$ versus carbon number, n , of analyte for HPLC on a polyfunctional C_{18} -bonded silica with pure methanol eluent at 25°C: *n*-alkanes (\square), methyl-*n*-alkanoates (\bullet) and *n*-alkanols (\circ). (Reprinted from Tchaplal A, Herson S, Lessellier E and Colin H (1993) General view of molecular interaction mechanisms in reversed-phase liquid chromatography. *Journal of Chromatography A* 656: 81–112, with permission of Elsevier Science.)

The ability of an analyte to take part in polar interactions is difficult to characterize by means of a single descriptor. Hence simple QSRR involving analyte polarity descriptors, e.g. dipole moments, are rare.

Normally in chromatography (excepting affinity chromatography) molecular shape effects on retention are of minor importance in comparison with the effects of molecular size and molecular polarity. In the case of planar/nonpolar PAH isomers, retention is linearly related to a shape descriptor (the degree of elongation of the analyte molecule).

There are numerous reports on good performance of the molecular connectivity index (Randić index) and its modifications in predicting retention of congeneric analytes, including isomers. The correlations are good when retention is on nonpolar stationary phases, but not when polar phases are involved. Whereas on the nonpolar phases the nonspecific dispersive interactions determine differences in retention among the analytes, the more specific polar interactions become discriminative in the case of polar phases (and polar analytes).

Using substituent electronic constants to derive simple QSRR with a real retention prediction ability has seldom succeeded. A wider application in that respect is found in Hansch substituent hydrophobic constants, π , and Rekker or Hansch–Leo fragmental hydrophobic constants, f . The sums of these constants (plus corrections due to intramolecular interactions) account well for retention in reversed-phase liquid chromatographic systems.

Regarding the latter systems, even better predictions are provided by an empirical parameter – the

logarithm of the *n*-octanol–water partition coefficient, $\log P$. Another useful empirical retention predictor appears occasionally to be boiling point, T_b , for example the boiling point of isomeric hydrocarbons in the gas chromatography.

Prediction of retention of variously substituted derivatives of parent compounds in a given separation system can be based on the Martin rule:

$$\log k_s = \log k_p + \sum_{i=1}^n \tau_i \quad [7]$$

In eqn [7] k_p is the retention parameter of a parent compound, k_s is the corresponding value for the derivative carrying *n* substituents and the summation represents the retention increments due to individual substituents τ_i . Having appropriate values for functional groups of interest, one needs only to determine retention of the parent structure to be able to calculate retention of a derivative. To get reliable predictions, correction factors are introduced in eqn [7] to account for mutual interactions between substituents (electronic, steric, hydrogen bonding). However, in the case of polyfunctional analytes, interactions between substituents make retention predictions of rather limited value.

A semiempirical description of reversed-phase HPLC systems, allowing for the prediction of the relative retention and selectivity within a series of analytes, has been developed by Jandera. The approach consists of determining the interaction indices and the structural lipophilic and polar indices. A suitable set of standard reference analytes is necessary to calibrate the retention (or selectivity) scale.

The multiparameter QSRR based on linear solvation energy relationships (LSER) possess a high predictive power regarding reversed-phase HPLC retention. The model developed by Abraham and co-workers to predict the *n*-octanol–water partition coefficient, $\log P$, appears to be useful also in the case of $\log k$ from reversed-phase liquid chromatography:

$$\log k = c_0 + c_1 V_x + c_2 \pi_2^H + c_3 \sum \alpha_2^H + c_4 \sum \beta_2^H + c_5 R_2 \quad [8]$$

In eqn [8] V_x is the so-called McGowan's characteristic volume, which can be calculated simply from molecular structure; π_2^H is the dipolarity/polarizability of the analyte, which can be determined through gas-chromatographic and other measurements; $\sum \alpha_2^H$ is the effective or summation hydrogen bond acidity; $\sum \beta_2^H$ is the effective or summation hydrogen bond basicity; and R_2 is an excess molar refraction, which

can be obtained from refractive index measurements and is an additive quantity. The LSER-based structural descriptors are available for a large number of compounds.

Experimentally determined ionic radius, I_r , and energy of ionization, E_i , accompanied by atomic mass, A_m , produce a three-parameter regression equation predicting capillary electrophoretic mobility of metal cations. The QSRR equation indicates that atomic mass approximates to the retardation factors (negative input to mobility) whereas the ionic radius is an approximate measure of the effective charge on the analyte. Energy of ionization can play the role of a secondary, but significant, correction factor to the effective charge. Unfortunately, there are no good QSRR to predict the CE retention of organic analytes.

A typical multiparameter approach to predicting retention of an unknown compound based on structural features and chromatographic properties of other representative compounds consists of generating a multitude of analyte descriptors that are next regressed against retention data. The structural descriptors are usually derived by computational chemistry methods for the energy-optimized conformations. Software systems have been developed that produce and process hundreds of quantum chemical, molecular modelling, topological and semiempirical additive–constitutive descriptors after sketching the molecule on the computer. Observing all the rules and recommendations for meaningful statistics, the minimum number of descriptors (uncorrelated) is selected that are needed to produce a QSRR equation with a good predictive ability. The descriptors that eventually serve to predict retention of new analytes are sometimes of obscure physical meaning. For example, it is difficult to ascribe definite physical sense to such descriptors reported in predictive QSRR as 'the surface area of the positively charged portion of the molecule divided by the total surface area' or 'total entropy of the molecule at 300 K divided by the number of atoms'. Nevertheless, for several groups of compounds, prediction of retention by means of QSRR is reliable enough for identification purposes, especially when there is no better alternative. Exemplary predictive QSRR are for polychlorinated dibenzofurans and biphenyls, anabolic steroids, stimulants and narcotics used as doping agents, barbituric acid derivatives, polyaromatic and nitrated polyaromatic hydrocarbons, etc.

There are QSRR of useful predictive potency that comprise only physically interpretable terms. Reversed-phase HPLC retention of simple aromatic solutes on typical octadecyl silica columns has been related to a molecular bulkiness descriptor (total energy), a polarity descriptor (local dipole) and the energy of the

highest occupied molecular orbital of analytes. Good prediction of liquid chromatographic retention of about 50 aromatic acids was realized using as regressors the calculated theoretical logarithm of the *n*-octanol–water partition coefficient ($\log P$), the dipole moment, the principal ellipsoid axes, the sum of the charges on the oxygen and nitrogen atoms, the energy of the highest occupied molecular orbital (HOMO) and the electrophilic superdelocalizability for the aromatic carbon atom.

In Figure 3 is illustrated the predictive performance of QSRR for 216 HPLC retention data points. The points are for 36 analytes chromatographed in six eluents on a diol stationary phase. The eluents were heptane containing 0.5% of tetrahydrofuran, dioxane, ethanol, propanol, octanol and dimethylformamide. In Figure 3 the $\log k$ data experimentally measured are plotted against the values predicted by eqn [9]:

$$\begin{aligned} \log k = & 0.100 \text{ polarizability (analyte)} \\ & - 0.400 \log P \text{ (analyte)} \\ & - 0.330 E_{\text{HOMO}} \text{ (analyte)} \\ & + 1.106 E_{\text{HOMO}} \text{ (eluent)} \\ & + 0.401 E_{\text{LUMO}} \text{ (eluent)} \end{aligned} \quad [9]$$

with the values $n = 216$, $R = 0.97$, $s = 0.097$ and $F = 655$. In this equation n is the number of data points used to derive regression equation, R is the multiple correlation coefficient, s is the standard error of estimate and F is the value of F-test of significance; E_{LUMO} denotes energy of the lowest unoccupied mo-

lecular orbital and E_{HOMO} is energy of the highest occupied molecular orbital.

Figure 3 reflects realistically the actual predictive power of QSRR. The predictive QSRR equations normally hold within the family of analytes for which they were derived and may be used for tentative identification of chromatographic peaks.

In recent years a three-dimensional quantitative structure–biological activity relationship method known as comparative molecular field analysis (CoMFA) has been applied to construct a 3D-QSRR model for prediction of retention data. The CoMFA 3D-QSRR model is obtained by systematically sampling the steric and electrostatic fields surrounding a set of analyte molecules and then correlates the differences in these fields to the corresponding differences in retention.

Several reports have recently appeared on predictions of retention data from structural descriptors by means of neural networks (NN). By now the predictions provided by NN are of similar reliability to those obtained from regression models.

QSRR and Molecular Mechanisms of Retention

The QSRR equations that comprise physically interpretable structural descriptors can be discussed in terms of the molecular mechanisms involved in the chromatographic process. There is evidence that different structural parameters of analytes account for retention differences in GC on polar versus nonpolar stationary phases. Also, the structural descriptors in

Figure 3 Plot of $\log k$ predicted by eqn [9] against experimental data determined on a diol column for 36 chalcone derivatives with heptane eluent containing 0.5% tetrahydrofuran, dioxane, ethanol, propanol, octanol or dimethylformamide. (Reprinted with permission from Azzaoui K and Morin-Alloy L (1996) Comparison and quantification of chromatographic retention mechanisms on three stationary phases using structure–retention relationships. *Chromatographia* 42: 389–395. Copyright Friedrich Vieweg & Sohn.)

QSRR equations that are valid for normal and for reversed-phase HPLC systems are different. In the case of apparently similar chromatographic systems, the differences in retentive properties of stationary phases may be reflected by the magnitude of the regression coefficients for analogous descriptors. Comparative QSRR studies are especially valuable when new chromatographic phases are introduced.

A general rule is that QSRR equations are characterized by two kinds of structural descriptors: one that accounts for the bulkiness or size of an analyte and one that encodes its polar properties. Size descriptors are always significant in GC on nonpolar phases and in reversed-phase HPLC, whereas the significance of polar descriptors increases as polarity of both the stationary phases and the analytes increases.

Publications give evidence that in GC on polar phases and in normal-phase (adsorption) liquid chromatography (HPLC and TLC) the chemically specific, molecular size-independent intermolecular interactions are assumed to play the main retention-determining role. For example, the HPLC retention parameters determined for substituted benzenes on porous graphitic carbon are described by QSRR equations comprising polarity descriptors but no bulk descriptors. Because, in general, it is difficult to quantify polarity properties precisely, the QSRR for GC on polar phases and for normal-phase HPLC are usually of lower quality than for GC on nonpolar phases and in reversed-phase liquid chromatography.

QSRR differentiate in a quantitative (statistical) manner stationary phase materials of different chemical nature. However, when the stationary phases that belong to the same chemical class are compared, such as hydrocarbon-bound silicas for reversed-phase HPLC, the results obtained are ambiguous.

The proper QSRR strategy aimed at objective characterization of differences in retentive potency of individual chromatographic systems should employ a well-designed set of test analytes. The analytes should be selected in such a way that, within the test set, the intercorrelations are minimized among the individual analyte structural descriptors. At the same time, the selection of test analytes should provide a wide range and even distribution of individual structural descriptor values. In addition, the series of analytes should be large enough to assure statistical significance of the QSRR equations but not too large so as to remain experimentally manageable.

Often the retention parameters of test analytes are first linearly regressed against the reference $\log P$ values from the *n*-octanol–water partition system. Good correlations obtained are usually interpreted as evidence of a partition mechanism operating in the chromatographic system under study.

Several QSRR studies aimed at comparison of retention mechanisms on individual alkyl silica reversed-phase materials for HPLC have employed LSER-based analyte parameters. It was observed generally that the most important analyte parameters that influence retention are bulkiness-related (molar volume, molar refraction) and hydrogen bonding basicity, but not hydrogen bonding acidity. The analyte dipolarity/polarizability appeared to be a minor but often significant factor. However, on poly(styrene-divinylbenzene) stationary phases the dipolarity/polarizability term provides an important positive input to QSRR.

The results of QSRR studies in which eqn [8] was applied to the retention parameters, $\log k_w$, from measurement on alkyl silica phases with methanol–water and acetonitrile–water eluents are instructive. The most significant parameters appeared to be hydrogen bond basicity (β_2^H) and McGowan volume (V_x) of analytes. The third significant parameter in QSRR equations is either dipolarity/polarizability (π_2^H) in the case of methanolic eluents or hydrogen bond acidity (α_2^H) in the case of acetonitrile-modified mobile phases.

The rationalization of these results might be as follows. The dispersive interactions of analytes (characterized by V_x) and hydrogen bonding interactions in which an analyte molecule is a hydrogen-bond acceptor (characterized by $\sum \beta_2^H$) significantly affect the retention of analytes in both water–methanol/stationary phase and water–acetonitrile/stationary phase equilibrium systems. However, in methanolic systems the third significant factor determining equilibrium is the ability of an analyte molecule to be preferentially attracted by polar molecules of methanol owing to the dipole–dipole and dipole-induced dipole interactions (characterized by π_2^H). In the systems containing acetonitrile, the π_2^H descriptor becomes insignificant in QSRR equations. Instead, the ability of the analyte to be preferentially attracted by the eluent owing to hydrogen bonding in which the analyte serves as a hydrogen bond donor (characterized by $\sum \alpha_2^H$) becomes more significant. The well-known hydrogen bond acceptor properties of acetonitrile manifest themselves in eqn [8] as a retention-decreasing term $k_4 \sum \alpha_2^H$ with a negative value of the k_4 regression coefficient.

Most readily interpretable would appear to be the molecular mechanism of retention in terms of QSRR equations comprising the parameters of analytes obtained from molecular modelling. One can easily assign physical meaning to van der Waals surface area or solvent-accessible molecular surface area (SAS) as differentiating the strength of dispersive interactions between the analyte and the molecules forming

chromatographic systems. Dipole moment (μ) should also account for differences among analytes regarding their dipole-dipole or dipole-induced dipole interactions. Energies of the lowest unoccupied molecular orbital (E_{LUMO}) and the highest occupied molecular orbital (E_{HOMO}) should explain the differences in the tendency of analytes to take part in the charge transfer interactions. Yet reliable QSRR employing these structural descriptors are rare and hold only for selected sets of analytes.

In QSRR concerning reversed-phase HPLC retention parameters, the net positive effects on retention are due to the analyte bulkiness descriptors. The dispersive attractions of an analyte are stronger with the bulky hydrocarbon ligand of the stationary phase than with the small molecules of aqueous eluent. The net effect on retention provided by dipole moment (or its square) is negative. This is because the dipole-dipole and dipole-induced dipole attractions are stronger between the polar (polarized) analyte and polar molecules of eluent than between the same analyte and the nonpolar hydrocarbon ligand of the stationary phase. Unfortunately, these types of QSRR are not precise enough to differentiate individual alkyl silica stationary phase materials in a quantitative, statistically significant manner. They are significant enough, however, to reflect the differences in retention mechanism operating in the reversed-phase and in the normal-phase HPLC systems or in GC on nonpolar and polar phases.

Factorial methods of data analysis (principal component analysis, correspondence factor analysis, spectral mapping analysis) provide classification of stationary phases based on retention data determined for short series of test analytes. Among the commercially available materials for HPLC those can be selected that possess closely similar retention properties. Also, a stationary phase with clearly distinctive properties can be identified, which can be useful for specific method development.

Chromatographic Methods of Determination of Hydrophobicity

Hydrophobicity or lipophilicity is understood to be a measure of the relative tendency of an analyte 'to prefer' a nonaqueous over an aqueous environment. The partition coefficients of the substances may differ if determined in different organic-water solvent systems but their logarithms are often linearly related. Octanol-water is a reference system that provides the most commonly recognized hydrophobicity measure: the logarithm of the partition coefficient, $\log P$. The standard 'shake-flask' method for determining partition coefficients in liquid-liquid

systems has several disadvantages. Having appropriate QSRR, the chromatographic data can be used to predict $\log P$. Many good correlations of reversed-phase liquid chromatographic (HPLC or TLC) parameters with $\log P$ have been reported for individual chemical families of analytes and chromatographic methods for assessing the hydrophobicity of drugs and environmentally important substances have officially been acknowledged and included in the *OECD Guidelines for Testing Chemicals*.

On the other hand, the partition chromatographic systems are not identical with the *n*-octanol-water partition system. Each chromatographic system produces an individual scale of hydrophobicity. Hence attempts to reproduce $\log P$ by means of liquid chromatography are only partially successful. Centrifugal countercurrent chromatography (CCCC) provides a better chance of mimicking $\log P$ but the inconvenience of this method and the need for special equipment hinder its wider application.

The versatility of chromatographic methods of hydrophobicity assessment can be attributed to the use of organic modifiers in aqueous eluents. Normally, the retention parameters determined at various organic modifier-water (buffer) compositions are extrapolated to zero organic modifier content. The extrapolated parameters ($\log k_w$ from HPLC and R_M^0 from TLC) depend on the organic modifier used.

Alkyl silica stationary phases and methanol-water eluent are most often used in hydrophobicity studies. The problem with these phases is that the hydrophobicity of nonionized forms of organic bases cannot be determined because of the chemical instability of silica-based materials at higher pHs (above about pH 8). Also, specific interactions of analytes with the free silanols of alkyl silicas disturb partition processes.

The limitations of standard reversed-phase materials have been partially overcome by introducing modern specially deactivated hydrocarbon-bonded phases, immobilized on alumina or zirconia supports and on polymeric materials. Using the latter two types of stationary phase materials one can determine HPLC retention factors under acidic, neutral and alkaline conditions. That way a universal, continuous chromatographic hydrophobicity scale can be constructed, as is the standard $\log P$ scale.

Hydrophobic properties of xenobiotics are assumed to affect their passive diffusion through biological membranes and binding to pharmacological receptors. If the hydrophobicity measuring system is to model a given biological phenomenon, then similarity of the component entities is a prerequisite.

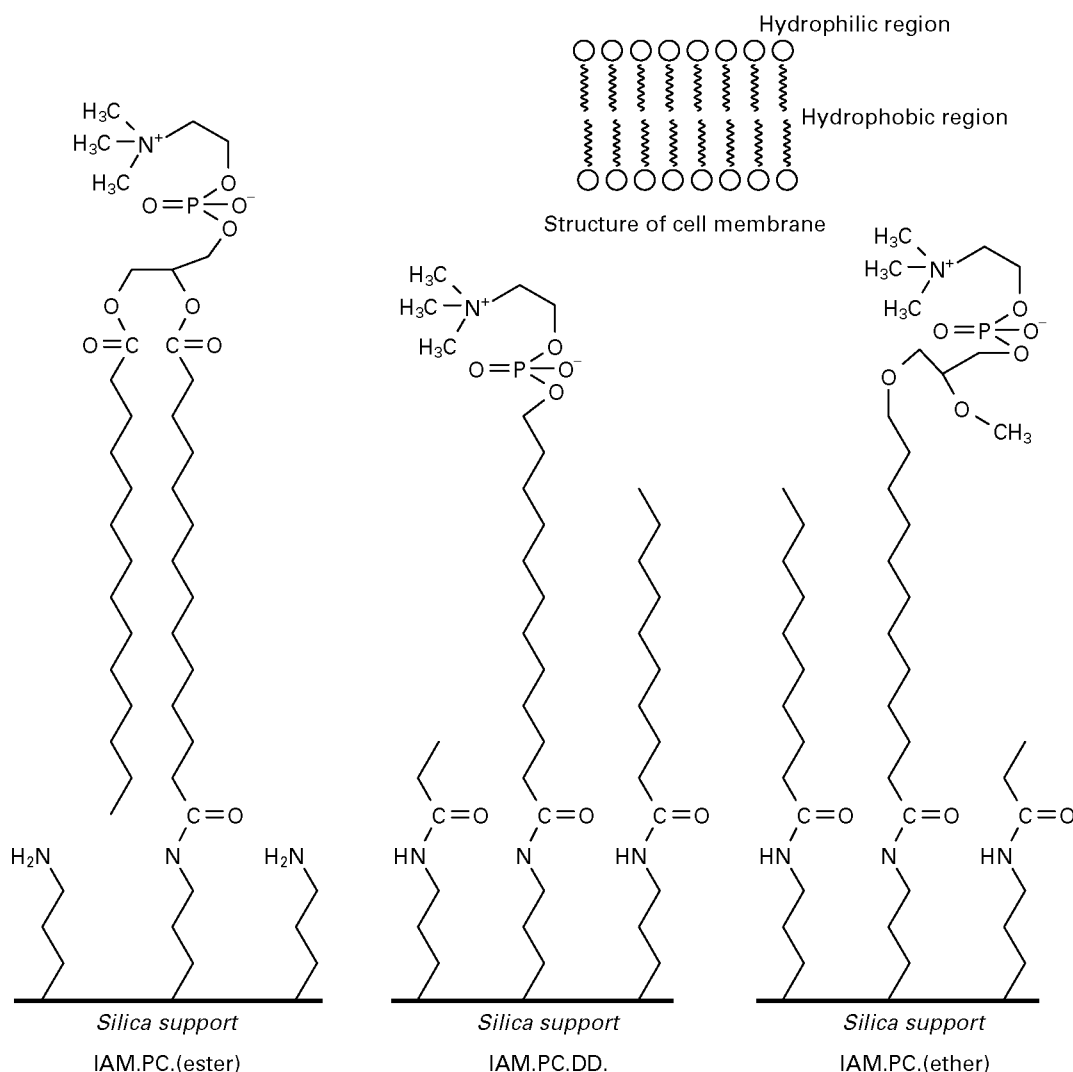

Figure 4 Chemical structures of ligands of three types of immobilized artificial membrane (IAM) columns of Pidgeon (Liu H, Ong S, Glunz L and Pidgeon C (1995) Predicting drug-membrane interactions by HPLC: structural requirements of chromatographic surfaces. *Analytical Chemistry* 67: 3550-3557. Copyright 1995 American Chemical Society.) and a schematic model of a biological membrane.

Hence the partition system to model the transport through biological membranes should be composed of an aqueous phase and an organized phospholipid layer. The immobilized artificial membranes (IAM) introduced by Pidgeon as a packing material for HPLC (Figure 4) appear to be reliable and convenient models of natural membranes.

Correlations between $\log k$ data determined on IAM-type columns and $\log P$ values are generally not high nor are the correlations between $\log k$ from IAM columns and $\log k_w$ determined by liquid chromatography employing standard stationary phase materials. This means that retention data determined on IAM columns contain information on the properties of analytes that is distinct from that provided by the *n*-octanol-water system and by the hydrocarbon-

silica reversed-phase columns. There is evidence that the hydrophobicity characteristics provided by IAM columns are better suited for modelling the pharmacokinetics of drug processes.

Retention Parameters in Predicting Bioactivity of Analytes

Biological processes of drug absorption, distribution, excretion and drug-receptor interaction are dynamic in nature as are the analyte's distribution processes in chromatography. The same fundamental intermolecular interactions determine the behaviour of chemical compounds in both biological and chromatographic environments. Modern techniques and procedures of HPLC and CE allow for inclusion

of biomolecules as active components of separation systems and QSRR processing of appropriate sets of chromatographic data can reveal systematic information regarding the xenobiotics studied. This information can be used to elucidate molecular mechanisms of pharmacological action and to facilitate rational drug design.

It is often sufficient to identify and employ a specific chromatographic system yielding hydrophobicity values of analytes best conforming to $\log P$ data. Normally, chromatographic systems that produce retention parameters less correlated to $\log P$ are discarded but information extracted from diversified retention data may be more appropriate for prediction of pharmacological properties of analytes than information based on an individual hydrophobicity scale. To extract meaningful information from diversified (yet often highly mutually intercorrelated) sets of data, multivariate chemometric methods of data analysis are employed. Large matrices of retention data determined for test series of analytes in many chromatographic systems differing in type of stationary and/or mobile phases, are processed by factorial methods, usually by principal component analysis (PCA). If two to three extracted abstract factors (principal components) account for most of the variability in a large set of retention data then the distribution of test analytes can be presented graphically. Clustering of analytes owing to similarity of their chromatographic behaviour in diverse separation systems is usually observed. If that clustering agrees with the pharmacological classification of the test agents, then recalculations are done after including the retention data for drug candidates. Indications on potential pharmacological activity of new analytes can be obtained even before biological experiments. This approach can facilitate preselection of drug candidates, especially among a multitude of compounds produced by combinatorial chemistry. The challenge is to design and select the chromatographic systems yielding retention data of sufficient classification potential.

Figure 5 shows the distribution of drugs belonging to several pharmacological classes on the plane determined by the first two principal components, which together account for 81.5% of the variance in the retention data measured in eight HPLC systems. The HPLC systems employed different stationary phases (standard and specially deactivated hydrocarbon bonded silicas, polybutadiene-coated alumina, immobilized artificial membranes and immobilized α_1 -acid glycoprotein). Methanol-buffer eluents of varying composition and pH were used. The clustering of analytes is consistent with their established pharmacological classification. Also, the partial overlap of

Figure 5 Pharmacologically consistent distribution scatterplot of drug classes on the plane determined by two first principal components extracted from a 8×83 (drugs \times HPLC systems) matrix of diversified retention data. Roman numbers denote: I, psychotropic drugs; Ia, inactive phenothiazines; II, β -adrenolytics; III, histamine H_1 receptor antagonists; IV, histamine H_2 receptor antagonists; V, drugs binding to α -adrenoceptors. (Reprinted from Nasal A, Buciński A, Bober L and Kaliszan R (1997) Prediction of pharmacological classification by means of chromatographic parameters processed by principal component analysis. *International Journal of Pharmaceutics* 159: 43–55, with permission of Elsevier Science.)

individual clusters is interpretable in terms of partially overlapping pharmacological properties of individual drugs.

There are individual processes of drug action that are satisfactorily modelled by HPLC on immobilized artificial membrane (IAM) columns. QSRR equations have been reported predicting several pharmacokinetic parameter of β -adrenolytic drugs from their $\log k$ parameters determined on IAM columns. Good predictions by means of $\log k_{IAM}$ have also been reported regarding antithaemolytic activity of phenothiazine neuroleptics. The human skin permeation of steroids also correlates better with $\log k_{IAM}$ than with $\log P$.

The $\log k_{IAM}$ alone will not suffice to predict binding of basic drugs to the serum protein, α_1 -acid glycoprotein (AGP). However, combining that parameter with atomic excess charge on aliphatic nitrogen, N_{ch} , and a size parameters, S_T , in a multiple regression equation results in a good prediction of AGP binding. The S_T parameter is the area of a triangle having one vertex on the aliphatic nitrogen and the two remaining vertices on the extremely positioned atoms in the drug molecule (Figure 6). The QSRR equation has

the form:

$$\begin{aligned} \log k_{\text{AGP}} = & 0.6577 (\pm 0.0402) \log k_{\text{IAM}} \\ & + 3.342 (\pm 0.841) N_{\text{ch}} \\ & - 0.0081 (\pm 0.0030) S_{\text{T}} \\ & + 1.688 (\pm 0.245) \end{aligned} \quad [10]$$

with the values $n = 49$, $R = 0.929$, $s = 0.163$, $F = 92$ and $p < 10^{-5}$.

Equation [10] may be useful as a first approximation to the relative binding of a drug to AGP without the need to perform biochemical experiments. It can help to identify structural features of the binding site of basic drugs on AGP (Figure 6). The site can be modelled as a conical pocket. Its internal surface contains hydrophobic regions at the base of the cone and an anionic region close to the apex of the cone. Protonated aliphatic nitrogen guides drug molecules towards the anionic region. Hydrophobic hydrocarbon fragments of the interacting drugs provide anchoring in the hydrophobic regions of the binding site. There is a steric restriction for the molecule to plunge into the binding site.

QSRR analysis of HPLC data determined on an immobilized human serum albumin (HSA) column helps to suggest the topography of two binding sites of different affinity to benzodiazepine enantiomers. Also, the mechanism of interaction of phenothiazine neuroleptics with melanin can be rationalized by means of QSRR analysis of HPLC retention data. Another QSRR study concerns interactions of drugs with immobilized keratin and collagen.

In general, QSRR analysis of retention parameters determined on immobilized biomacromolecules can yield reliable predictions of activity and identification of the required binding structural properties of

drugs and drug candidates. The approach appears especially promising now that biotechnologically produced pharmacological receptors are becoming available.

Concluding Remarks

In 1991 Giddings wrote 'Because pure theory is impractical, progress in understanding and describing molecular equilibrium between phases requires a combination of careful experimental measurements and correlations by means of empirical equations and approximate theories'. This has been realized in a systematic manner over a period of 20 years through QSRR analysis. During that time a consistent research strategy has been developed and established within the area. Easy access to computers equipped with advanced statistics and molecular modelling software has ensured rapid progress and engendered a wide interest in QSRR among chromatographers and other specialists.

QSRR are employed by analytical chemists to help identify unknown members of individual classes of analytes of pharmacological, toxicological, environmental or chemical interest. At the same time, QSRR of good retention prediction capability help to identify structural descriptors for analytes that provide acceptable estimates of properties other than chromatographic ones. In this way, chromatographic systems allowing for fast and convenient evaluation of analyte hydrophobicity can be identified. Also, QSRR confirm the suitability of the LSER-based descriptors for property predictions.

Well-designed QSRR studies are helpful in identifying the structural features within a family of analytes that affect retention in a given separation system. In this way molecular mechanisms of retention may be explained. With a designed test series of analytes the QSRR derived for retention data determined in individual separation systems provide objective, numerical characteristics for these separation systems. This is especially useful for quantitatively comparing retention properties of various stationary phase materials.

Chromatographic retention data can be employed to predict pharmacological properties of analytes. By employing chromatographic systems comprising biomacromolecules, large amounts of data can be obtained that reflect differences among analytes with regard to their interactions with given biomacromolecules. These data can be used to derive QSRR explaining the mechanism of drug-biomacromolecule interactions. In effect, the topography of binding sites for drugs on individual biomacromolecules can be characterized. By employing

Figure 6 Mode of binding of the organic base drugs derived from QSRR analysis of HPLC data determined on an immobilized α_1 -acid glycoprotein column. (Adapted with permission from Kaliszan R, Nasal A and Turowski M (1995) Binding site for basic drugs on α_1 -acid glycoprotein as revealed by chemometric analysis of biochromatographic data. *Biomedical Chromatography* 9: 211–215. Copyright John Wiley & Sons Limited.)

biotechnologically acquired pharmacological receptor proteins to generate drug-receptor interaction data and by applying QSRR analysis, the preselection of drug candidates can be facilitated and experiments on animals reduced.

REACTIVE DISTILLATION

S. M. Mahajani, Monash University, Clayton, Victoria, Australia

S. P. Chopade, Michigan State University, East Lansing, MI, USA

Copyright © 2000 Academic Press

Introduction

Reactive distillation is a combination of separation and reaction in a single process. Commercial reactive distillation processes for the manufacture of methyl *t*-butyl ether (MTBE) and methyl acetate were successfully commissioned in 1981 and 1983, respectively. These processes have a distinct edge over their conventional predecessors. The reactive distillation process is particularly advantageous in the case of reversible reactions where the conversion is limited by thermodynamic equilibrium. Some of the important benefits of reactive distillation are: reduced capital cost; employment of low mole ratios of reactants; energy saving owing to utilization of the heat of reaction; and automatic temperature control and elimination of hot spots. The commercial process of MTBE manufacture has shown that heterogeneous catalysts such as ion exchange resins can be advantageously used in reactive distillation columns. Innovative techniques of confining the small size resin particles (0.3–2 mm) in the column, allowing efficient solid–liquid contact and high void fraction, have been

developed by CDTech, Sulzer, Koch Engineering and BASF. An alternative approach is to prepare a catalyst in the form of conventional column packing and pack it directly into the reactive distillation column.

Recognizing the potential of reactive distillation for a particular process is a difficult task, as not all the reactions can be conducted effectively in this way. Once its potential has been identified, the next step is to design the reactive distillation column for the required task. The simultaneous existence of multiple processes such as mixing, mass transfer and reaction are involved, and the design method requires thorough knowledge of both chemical and physical equilibria as well as the reaction kinetics. Graphical representations of liquid phase compositions, called residue curve maps or distillation maps, are commonly used to analyse the reactive distillation process. Though some efforts have been made to study the underlying theory of the design method, the work is still at its preliminary stage. Another approach to understanding the behaviour of this process is to perform computer simulations and predict the performance of a column of known configuration.

In this article the important aspects of commercial reactive distillation processes of MTBE and methyl acetate manufacture are described in detail. Recent trends in the experimental and theoretical investigations in this area are also outlined. The potential importance of reactive distillation in some industrial

processes such as hydrolysis of methyl acetate and recovery of chemicals from aqueous streams is discussed.

MTBE Production

The area of particular interest where reactive distillation can be used is the production of fuel ethers such as MTBE. Gasoline reformulation using these ethers as environmentally benign octane boosters has been driven by various Clean Air Acts, which have boosted MTBE production to a new level. By 2001 the production of MTBE is expected to be 25×10^6 tonnes per annum worldwide. *t*-Amyl methyl ether (TAME) and ethyl *t*-butyl ether (ETBE) are also emerging as promising fuel additives. In addition to its property as an antiknock agent to enhance the octane number of the fuel, MTBE improves the water tolerance limit of the fuel and has a higher calorific value than that of other additives such as methanol.

Another important aspect of carrying out the etherification to near complete conversion is its efficient use in separating the *iso*-olefins from the refinery stream containing both normal and secondary butenes (C_4 or C_5), which are otherwise very difficult to isolate. A reactive distillation column can handle the mixed olefins quite effectively and exploits the presence of inert butenes to improve performance. This separation is necessary because *n*-butenes are required in the pure form for homopolymerization and as a feed for the oxidative production of butadiene.

Reaction Details

MTBE is a product of the liquid-phase reaction of isobutylene and methanol, catalysed by a strong acidic macroreticular ion exchange resin. The reaction is highly selective, so that methanol reacts only with isobutylene in the presence of other C_4 olefins [1].

$$\Delta H_{298}^0 = -37.7 \text{ kJ mol}^{-1}$$

The favourable temperature and pressure ranges for the reaction to occur are 323–373 K and 5–15 atm, respectively. The useful side reactions are the dimerization and oligomerization of isobutylene and butadiene as well as the formation of codimers. Since, until recently, only butadiene-extracted C_4 refinery streams were used for MTBE production, the only important by-product is diisobutylene, which consists of the isomers 2,4,4-trimethyl-1-pentene and 2,4,4-

trimethyl-2-pentene. The other side reactions, which are of less importance, are formation of *t*-butanol by reaction of isobutylene with water present as a feed impurity, the formation of traces of dimethyl ether by methanol condensation, and the double bond isomerization of 1-butene. Amberlyst 15®, a macroporous cation exchange resin, is widely used as a catalyst for this reaction. Numerous investigations on the kinetics of this reaction system have been reported in the literature. A model based on systematic studies of reaction kinetics (eqn [1]) and equilibrium of this system incorporating the activities of the compounds has been developed and is used by many investigators for column simulation studies.

$$r = m_{\text{cat}} q_{\text{acid}} k_f \left(\frac{a_{\text{IB}}}{a_{\text{MeOH}}} - \frac{1}{K_{\text{eq}}} \frac{a_{\text{MTBE}}}{a_{\text{MeOH}}^2} \right) \quad [1]$$

In eqn [1], m_{cat} is the catalyst loading, q_{acid} is the ion exchange capacity and a_i is the activity coefficient of the corresponding component (IB, isobutylene, MeOH, methanol). The forward reaction rate constant k_f and the equilibrium constant K_{eq} have been fitted experimentally. As a result of the high polarity of methanol, the reaction mixture is highly nonideal and involves formation of two binary azeotropes and one ternary reactive azeotrope. The activities of the components can sometimes be up to 20 times their mole fractions.

Commercial Process

Conventional processes for the manufacture of MTBE (see Figure 1) use a catalytic reactor with a slight excess of methanol (methanol/isobutylene = 1.05–2). The products correspond to the near-equilibrium conversion of about 90–95%. The reaction mixture is separated using distillation, but suffers from complications resulting from the formation of binary azeotropes methanol–MTBE and isobutylene–methanol. The unreacted isobutylene is also difficult to separate from other volatile C_4 products. With the reactive distillation process, almost complete conversion of isobutylene is obtained, thereby eliminating the separation and recycle problems. Figure 2 provides a schematic representation of this process. A fixed-bed pre-reactor is used to achieve near-equilibrium conversion. The product stream equivalent to the equilibrium conversion is fed to the reactive distillation column, wherein, the residual amount of isobutylene is reacted with methanol. The reactive distillation column is composed of three sections, the middle of which is a reactive zone packed with a solid catalyst. The top nonreactive rectifying section performs the separation of inert gases and

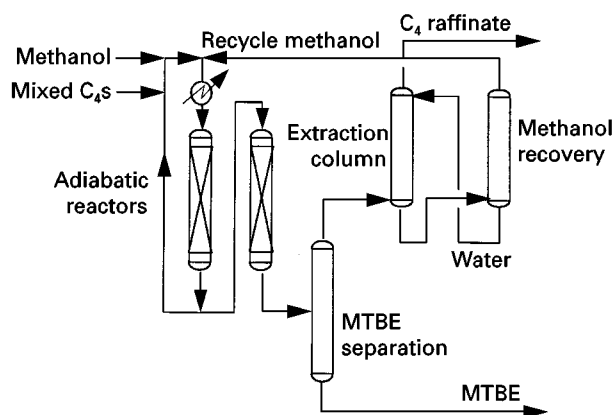

Figure 1 Conventional process for MTBE manufacture.

excess methanol, while the bottom section separates out MTBE in pure form. The boiling points of MTBE and methanol are 328 K and 337.5 K, respectively. This may seem surprising, as MTBE is the bottom product while unreacted high boiling methanol is collected through the distillate. The behaviour is caused by the formation of an MTBE-methanol low boiling azeotrope, which lifts methanol from the stripping section of the column.

The pioneering work to commercialize this technology was performed by Smith from Chemical Research and Licensing Company, who has been awarded several patents for different catalyst structures, column internals design and flow schemes. Some patents have also been assigned to researchers from ELF who claim to have used alternating catalytic and noncatalytic zones successfully to carry out the etherification. The efforts in these studies were directed towards minimizing the pressure drop in the catalyst bed and providing maximum residence time

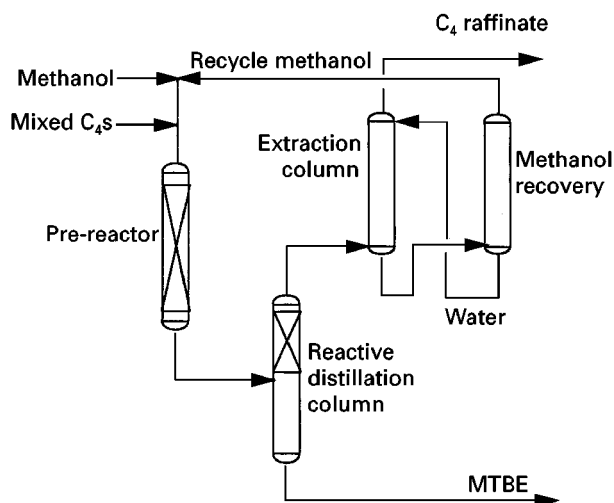

Figure 2 Reactive distillation process for MTBE manufacture.

for the liquid in the catalytic zone. This was achieved by providing separate free passage to the up flowing vapour stream either by packing the catalyst in the downcomers or by providing annular space in the catalyst bed, thereby isolating reaction and distillation zones in a single column. UOP, Koch Engineering and Hüls AG have jointly developed the Ethermax process for producing ethers by reactive distillation. The process uses Koch Engineering's Katamax packing, where a solid acid catalyst is confined in screen envelopes.

Simulation Studies

Following the successful commercialization of the MTBE process, numerous studies simulating a catalytic distillation column have appeared in the literature. The basic idea behind simulation studies is to predict the overall conversion of either isobutylene or methanol, and examine the product purity at a steady state for a known column configuration and feed composition. Various software packages such as ASPEN PLUS, SPEEDUP, etc, have been used effectively for this purpose.

The interesting discovery of multiple steady states for a column operated under identical conditions has attracted the attention of many researchers in the recent past. Several studies examining the reasons for the existence of these steady states have been reported. Experimental findings confirmed this fact and showed that the same column configuration operated under similar conditions can give rise to two different conversions. Simulation studies using an ASPEN PLUS flowsheet simulator for a column with a total of 17 reactive and nonreactive stages, operated at 11 atm with two different feed streams of methanol and butenes, result in either 36% or 99% isobutylene conversion when methanol is fed to the 10th stage. The methanol feed plate was varied by following either top-to-bottom or bottom-to-top sequence and it was found that only at certain feed plates (9–12) were multiple conversions realized (see Figure 3). The steady-state conversion in this multiplicity region depends upon which sequence is followed to simulate the column. In the upgoing sequence low conversions are obtained, while the downgoing sequence is associated with high conversions. Subsequent efforts on column simulation have confirmed this finding. Installation of the methanol feed at more than one location has been suggested to avoid the unwanted steady state caused by column misoperation.

A mechanistic explanation has been provided as to why MTBE production by reactive distillation may yield multiple solutions. It was found that the initial estimates for temperature and composition profiles

Figure 3 Steady-state multiplicity behaviour of the MTBE process.

decide whether a steady-state simulation would converge to a high conversion or a low conversion solution. In order to obtain a high conversion solution, the lower section of the column must contain sufficient MTBE to lift the entire amount of methanol to the reactive zone. Second, in the reactive zone, the reaction mixture must be diluted to avoid a substantial amount of MTBE decomposition. Initial estimates of the composition at the lowest stage in the reactive zone are crucial in deciding the nature of the steady state. This is expected to be due to the inherent coupling between 'lift' and 'dilution' effects that takes place on this stage.

Recent simulation studies on reactive distillation of MTBE and TAME indicate two types of multiple steady states. The first, discussed above, arises out of the interaction between reaction and vapour-liquid equilibrium. The second multiple steady state is related exclusively to the chemical reaction and arises because of the highly nonlinear concentration dependence of methanol activity at low operating pressures. The only experimental evidence of multiple steady states reported so far comes from work on etherification for TAME synthesis in a pilot plant of Nestle Oy. It is therefore necessary to perform dynamic simulations during the first steps of the design process in order to avoid dynamic surprises.

Another interesting finding of MTBE simulation studies is the oscillatory behaviour of the reactive distillation column. Sustained oscillations of boiling temperature and reflux have been reported in experimental studies on reactive distillation. It has been proved that the nonreactive and nonideal interactions

Methyl Acetate Production

Methyl acetate is another high volume commodity chemical that is manufactured commercially using reactive distillation. It finds applications as an intermediate in the manufacture of a variety of polyesters such as photographic film base, cellulose acetate, Tenite cellulosic plastics and Estron acetate.

Reaction Details

The reaction of methanol and acetic acid to give methyl acetate (reaction [III]) has equilibrium limitations.

$$\Delta H_{298}^0 = -8.0 \text{ kJ mol}^{-1}$$

$$K_{\text{eq}} = \frac{a_{\text{MeOAc}}a_{\text{H}_2\text{O}}}{a_{\text{AcOH}}a_{\text{MeOH}}} = 5.2 \quad [2]$$

Equation [2] gives the equilibrium constant K_{eq} as a function of the activity coefficients a_{MeOAc} (methyl acetate), $a_{\text{H}_2\text{O}}$ (water), and a_{AcOH} (acetic acid).

Thus the reaction product will contain all four components even if one of the reactants is used in excess. The reaction can be conducted in the temperature range 310–393 K and at a pressure of 1 atm. The only important side reaction is the formation of dimethyl ether by the condensation of methanol. This reaction is predominant at high temperatures.

Though the reaction has been commercialized in a reactive distillation column, it is surprising that a systematic study on the kinetics of this reaction in the presence of sulfuric acid as catalyst is not evident in the open literature. As in the MTBE system, the rate expression in the form of activities is strongly preferred because the high polarity of water and methanol compared to that of methyl acetate leads to strongly nonideal solution behaviour. Because of the commercial success of reactive distillation and the proven potential of the ion exchange resins, some efforts have been made to propose a rate expression for an ion exchange resin-catalysed reaction. The expression for the rate, r , based on kinetic data generated over a range of molar feed ratios more typical of reactive distillation conditions, is given by:

$$r = \frac{k(a_{\text{HOAc}}a_{\text{MeOH}} - a_{\text{MeOAc}}a_{\text{H}_2\text{O}}/K_{\text{eq}})}{(1 + K_{\text{HOAc}}a_{\text{HOAc}} + K_{\text{MeOH}}a_{\text{MeOH}} + K_{\text{MeOAc}}a_{\text{MeOAc}} + K_{\text{H}_2\text{O}}a_{\text{H}_2\text{O}})} \quad [3]$$

between methanol and isobutylene are responsible for these effects.

where k is the rate constant, K_{eq} is the equilibrium constant and the K_i s are the adsorption coefficients

involved in the Langmuir–Hinshelwood/Hougen–Watson model (HOAc, methyl acetate, MeOH, methanol; MeOAc, methyl acetate, H₂O, water). The expression has been successfully used to verify the experimentally observed residue curve maps of this system. The residue curve maps shows no distillation boundaries and hence, ultrahigh purity methyl acetate and water can be obtained through a proper design of reactive distillation column.

Commercial Process

Conventional processes before the 1980s used multiple reactors with a large excess of one of the reactants to achieve high conversion of the other. The product is difficult to purify because of the formation of methyl acetate–methanol and methyl acetate–water azeotropes. Different means to break the methyl acetate–methanol azeotrope were employed, such as use of several atmospheric and vacuum distillation columns or extractive distillation. A typical process contained two reactors and eight distillation columns, making it complex and capital intensive.

Eastman Kodak has developed a reactive distillation process for the manufacture of high purity and ultrahigh purity methyl acetate. The remarkable factor is that, in spite of the reaction having unfavourable equilibrium limitation, high purity product is obtained using a near-stoichiometric mole ratio of methanol and acetic acid. The reactive distillation column used in the process is shown in **Figure 4**. In order to explain the process, the column can be divided in four stages starting from the top as: (1) methyl acetate enrichment; (2) water extraction; (3) reaction; and (4) methanol stripping. The reaction occurs in the middle section (section 3) in a series of countercurrent flashing stages with sulfuric acid as the catalyst. In section 2, acetic acid acts as an extracting agent and extracts water (breaking the methyl acetate–water azeotrope) and some methanol. Acetic acid and methyl acetate are separated above the acetic acid feed, in the methyl acetate-enriching section (section 1), allowing pure methyl acetate to be recovered as the overhead product. Methanol is stripped from water in the bottom section (section 4) and water is the bottom product. Some intermediate boiling compounds are formed because of the impurities present in feed. Hence, a small stream is withdrawn just above the catalyst feed point and treated separately in an impurity-removal system. The impurities are stripped and concentrated, and the methanol + methyl acetate stream is recycled to the reaction zone. The reactive distillation column has been successfully operated at a near-stoichiometric mole ratio of acetic acid and methanol, yielding high

Figure 4 Reactive distillation process for methyl acetate manufacture.

purity methyl acetate as the product. The whole process is integrated in a single column, eliminating the need for a complex distillation column system and recycle of the methanol–methyl acetate azeotrope. A single reactive distillation column at Eastman Kodak's Tennessee plant produces 180 000 metric tons per year of high purity methyl acetate. The composition profile of the column shown in **Figure 5** demonstrates that the methyl acetate can be manufactured in a single column without need for additional purification steps.

Hydrolysis of Methyl Acetate

Methyl acetate–water mixture is produced in large quantities from purified terephthalic acid (PTA) plants. The manufacture of poly(vinyl alcohol) (PVA) also produces large quantities of methyl acetate (1.68 kg per kg PVA). Since methyl acetate is a comparatively low value solvent, it has to be sold at a lower price; hence it would be a better idea to hydrolyse it economically and recover methanol and acetic acid for reuse in the process.

Conventional processes for the hydrolysis of methyl acetate use a fixed-bed reactor followed by a complex arrangement of several distillation/extraction columns. The conversion is limited by unfavourable equilibrium (equilibrium constant 0.14–0.2) and a large amount of unconverted methyl

Figure 5 Composition profile in methyl acetate reactive distillation column.

acetate has to be separated and recycled. A schematic diagram of a typical conventional process is given in **Figure 6**. The reaction is carried out in a fixed-bed reactor and the product stream contains all four components. Four additional columns are required to separate methanol and acetic acid streams and recycle unconverted methyl acetate, along with methanol, to the reactor.

The above has shown how reactive distillation simplifies the process in the case of the manufacture of methyl acetate. A similar concept can be applied to the hydrolysis reaction. A reactive distillation process has been developed on a laboratory scale for the hydrolysis of methyl acetate using an ion exchange resin catalyst in a special form. Converting the process from conventional to reactive distillation offers the possibility of eliminating many complicated steps. The use of solid acid catalysts obviates the need for recovery of the spent acid and the use of exotic

construction materials. Resin was moulded into 7 mm × 7 mm pellets using polyethylene powder. The distillation column was directly packed with these pellets, which played the role of both catalyst and packing.

A schematic diagram of the proposed reactive distillation process is shown in **Figure 7**. Water is fed at the top of the reactive section and methyl acetate is introduced at the bottom of the reactive section. The column is operated under total reflux of methyl acetate-methanol azeotrope. The stripping section strips all the methyl acetate and the bottom product is essentially free of methyl acetate. The bottom product, which now contains only methanol, water and acetic acid, can be easily separated using two distillation columns in series giving methanol and acetic acid as products. Thus, this process eliminates two main pieces of equipment from the conventional process: (1) a water wash column for the separation of methanol from methyl acetate, and (2) a methanol-enriching

Figure 6 Conventional process for hydrolysis of methyl acetate.

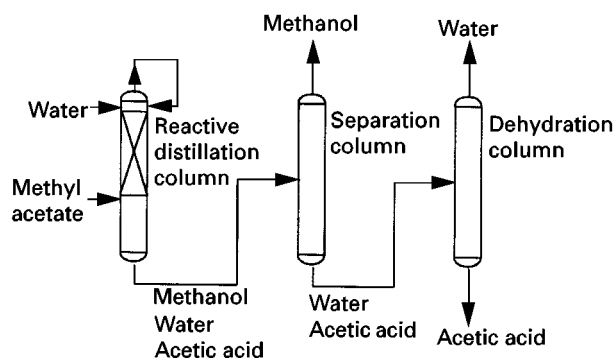

Figure 7 Reactive distillation process for hydrolysis of methyl acetate.

column for recovery of water-diluted methanol. Conversions to the tune of 99% are achieved in this process. The estimated heat savings are 50% that of the conventional process.

Recovery and Purification of Chemicals

The esterification reaction has also been successfully employed for the recovery of acetic acid from aqueous streams. Dilute acetic acid is produced in large quantities in many processes, such as the manufacture of cellulose esters, terephthalic acid and dimethyl terephthalate; and also in reactions such as acetylation and nitration. The recovery of acetic acid from these streams is a daunting problem. The conventional methods for recovery are azeotropic distillation, simple distillation and liquid-liquid extraction. With the advent of reactive distillation processes, esterification of acetic acid with methanol seems an attractive alternative. Laboratory experiments have been carried out to recover acetic acid in a reactive distillation column. The column contained commercially available ion exchange resin along with Rashig rings. The use of a solid acid catalyst offers noncorrosive conditions so that a less expensive construction material can be used. Up to 84% recovery of acetic acid as methyl acetate was achieved. Hoechst Celanese Corporation has recently described a reactive distillation process for the recovery of acetic acid from aqueous solutions as methyl acetate. With the use of acidic ion exchange resin as catalyst, more than 90% recovery from 5–30% aqueous acetic acid is claimed. They also suggest the use of Koch Engineering's Katamax packing as catalyst.

Reactive distillation can be applied for the recovery of many other chemicals from dilute streams. The polymer industry is often faced with the challenge of treatment of aqueous formaldehyde solutions, as it is a nuisance to the environment and it is difficult to

remove trace quantities of formaldehyde. Reactive distillation with methanol, ethanol or ethylene glycol not only brings down the formaldehyde concentration to the ppm level, but also yields useful acetal products. Similarly, nonboiling chemicals such as glyoxal and glyoxylic acid can be recovered from their aqueous solutions through the formation of their corresponding acetals or esters, which can be separated by distillation. CDTech has recently developed a reactive distillation process for hydrodesulfurization, called the CDHDS process, which is aimed at producing low sulfur fuels to meet stringent future environmental regulations at the lowest cost.

Reactive distillation has reportedly been employed for the purification of bisphenol A of polycarbonate grade, where impurities in the form of carbonyl compounds such as acetone, mesityl oxide, hydrotopraldehyde, etc., have to be reduced from about 3000 ppm to <10 ppm. A continuous reactive distillation column has been claimed to be a versatile method to achieve this objective.

Concluding Remarks

Reactive distillation offers several benefits over conventional processes for MTBE and methyl acetate manufacture. The commercial success of MTBE manufacture by reactive distillation has led to numerous investigations in the recent past on almost every aspect of this process. The generation of kinetic and equilibrium data at boiling temperatures, simulation and design studies, control strategies and identification of new reactions as candidates for reactive distillation, are some of the areas being investigated. Simulation studies of catalytic distillation for etherification have highlighted the important aspects of steady state multiplicity. This concept carries a special significance and plays an important role in design methods. Future work on simulation will see other reactions displaying this unusual phenomenon. Eastman Kodak has demonstrated the feasibility and advantages of reactive distillation at the commercial scale for methyl acetate manufacture. The process has scope for improvement in the sense that solid acid catalyst can be employed instead of sulfuric acid. Different techniques of confining the small beads of ion exchange resin in fibre glass cloth, wire mesh or structured packing have been developed. These catalysts offer very good vapour-liquid contact and activity but replacing the deactivated catalyst would be labour-intensive and time-consuming. The future focus should be on development of a catalyst in the form of a conventional column packing, such as Raschig rings, which would have good mechanical strength, activity and stability under the reaction conditions. Reactive

distillation may find a place in many other processes such as hydrolysis of methyl acetate, recovery of carboxylic acid from their aqueous solutions, hydrosulfurization and purification of phenols.

RESINS AS BIOSORBENTS: ION EXCHANGE

Introduction

The term biosorbent is usually applied to solid polymeric media employed in the purification, separation or isolation of biotechnological products. To assure

efficient sorption, these materials must meet certain requirements: they must have a high sorption capacity combined with ease of regeneration, good kinetic properties and mechanical stability over many sorption-regeneration cycles. Both ion exchange resins and their precursors, the inert polymer matrices, are extensively used to isolate fermentation products, including low molecular weight compounds, such as acetic acid, and high molecular weight compounds, such as enzymes and proteins.

Ion exchange resins have been traditionally used in water treatment technologies, for example for desalination and softening and for wastewater treatment. Their first application to pharmaceuticals may be dated to the 1950s and 1960s, although the greatest surge in interest in terms of papers and patents published occurred in the period 1960–75.

Pharmaceuticals

Of the various pharmaceutical products processed by ion exchange technologies, antibiotics are probably the most important. Because antibiotics mostly consist of charged molecules, they lend themselves readily to isolation with ion exchange resins, and with cation exchangers in particular. In January 1945, Van Dolah, Christenson and Shelton filed a US patent application claiming the use of organic cation exchangers for the purification of streptomycin and streptothricin. First to be used for this purpose were the phenol-sulfonic acid-type cation exchangers (Amberlite IR-100, Ionac C-200, Dowex 30). These were followed by high capacity carboxylic acid exchangers for commercial applications (Amberlite IRC-50). Both groups are characterized by a gel structure. They have no open pores in the dry state, but when placed in contact with aqueous solutions they undergo swelling and acquire the ability to uptake large ions.

Commercialization of the macroporous sorbents of the Amberlite XAD series by Rohm and Haas in the 1960s was a revolutionary step in ion exchange technology and opened up new possibilities for the isolation of antibiotics. Macroporous sorbents had the necessary mechanical strength, provided large surface areas for sorption, and had appropriate pore sizes for rapid transport. Macroporous resin sorbents such as the polyaromatics Amberlite XAD-4, -16 and -1180, Diaion HP20, media consisting of aliphatic esters (Amberlite XAD-7) and nitrated aromatics (nitrated Amberlite XAD-16) were recommended for large scale application for antibiotics.

Vitamins constitute another class of pharmaceuticals that are purified by ion exchange resins. Vitamin B₁₂, for example, is produced by microbial fermentation and can be separated from the broth using a carboxylic acid exchanger.

Proteins are based on copolymers of amino acids and may thus be regarded as polyionic materials. At a given pH they bear either a positive or a negative charge depending on their isoelectric point. Proteins are therefore eminently suitable for isolation by ion exchange technology. Exchangers based on matrices consisting of cross-linked polyacrylic and phenol-formaldehyde polymers have been used for large scale protein purification. However, the traditional ion exchangers are generally unsuitable for the adsorption of proteins due to their hydrophobicity, high charge density and high degree of cross-linking, which result in low protein capacities and a tendency towards denaturation of sorbed molecules. After the introduction in 1956 of the first ion exchanger specifically designed for proteins, a number of highly hydrophilic polysaccharide matrices have been proposed, all of them less rigid and more hydrophilic than the polystyrene type of biosorbents.

Synthesis of Resins

Today's ion exchange technology is based on organic polymer matrices. The typical spherical ion exchange beads are made by suspension polymerization of styrene with divinylbenzene to form an insoluble polymer gel. The mixture of monomers to which an initiator of radical polymerization has been added is stirred into an aqueous suspension under conditions designed to give the desired droplet size. This mixture is heated for several hours to yield solid spherical beads, which are then treated with concentrated sulfuric acid at about 80°C to obtain cation exchange resin. The final product is a sulfonated cross-linked polystyrene – the strong-acid cation exchanger most widely used commercially. It has a capacity of 5.25 mmol g⁻¹ calculated for oven-dried resin. The structural formula of the resin is given below (Structure 1), together with the formula of a weak-acid cation exchanger based on acrylic acid copolymerized with DVB (Structure 2).

Anion exchange resins are produced by a two-step process. First, chloromethylation is applied to introduce chloromethyl groups. The second step is amination. When a tertiary amine such as trimethylamine is used, the product is a strong-base quaternary ammonium compound (Structure 3). This resin is the anionic equivalent of the sulfonic cation exchange materials. The capacity of a typical strong-base resin is 3.9–4.2 mmol g⁻¹ of dry resin. The use of a secondary amine, such as dimethylamine or other multifunctional amine, gives various weakly basic resins, for example the one shown in Structure 4.

The resins mentioned above are among those most commonly used as ion exchangers. However, a wide range of resins tailored for specific needs is available; further information may be found in commercial catalogues as well as in relevant monographs. For

illustration, a list of synthetic resins manufactured by Mitsubishi and designed for protein separation is given in Table 1, together with the relevant recommendations.

As an alternative to the highly hydrophobic organic polymeric matrices, ion exchange materials for biological compounds have also been developed from cross-linked dextran, agarose and beaded crystalline cellulose polymers. The functional groups typically added to such matrices are shown below.

Anionic functional groups

Aminoethyl (AE)	$\text{---OCH}_2\text{CH}_2\text{NH}_3^+$
Diethylaminoethyl (DEAE)	$\text{---CH}_2\text{CH}_2\text{N}(\text{CH}_2\text{CH}_3)_2$
Quaternary aminoethyl (QAE)	$\text{---OCH}_2\text{CH}_2\text{N}^+(\text{C}_2\text{H}_5)_2\text{---CH}_2\text{CH}(\text{OH})\text{CH}_3$

Cationic functional groups

Carboxymethyl (CM)	$\text{---OCH}_2\text{COO}^-$
Phospho	$\text{---PO}_4\text{H}_2^-$
Sulfopropyl (SP)	$\text{---CH}_2\text{CH}_2\text{CH}_2\text{SO}_3^-$

DEAE-cellulose, an anion exchanger containing diethylaminoethyl groups attached to the cellulose, is applied extensively. An exchanger of this type having a content of basic groups of only 1 mmol g⁻¹ adsorbs three-quarters of its own weight of bovine plasma albumin from 0.2% solution in 0.01 mol L⁻¹ sodium phosphate at pH 7.0. CM-cellulose, a cation exchanger, which contains carboxymethyl groups, adsorbs its own weight of horse carbon monoxide haemoglobin from 0.2% solution in 0.01 mol L⁻¹ sodium phosphate at pH 6.0. Cellulose ion exchangers with improved characteristics are now available, and numerous studies on their use in

the separation of biologicals have been reported in the last 5 years.

Characteristics of Resins

Selection of the exchange resin for a given application is a process of compromise based on examination of many factors, such as the polar nature of the sorbate, the size of the sorbate, resin capacity, equilibrium relationships, elution properties and flow characteristics.

Adsorption Isotherm

In order to design a purification process based on an ion exchange technique, it is essential to know something about the capacity of the exchanger. Equilibrium sorption capacity is commonly determined with the help of the sorption isotherm, which gives the sorption uptake (q) and the final equilibrium concentration of the residual solute in solution (c). Sorption isotherms are measured by placing solutions with different concentrations of solute in contact with a known weight of the resin at a constant temperature until equilibrium is attained. Calculation of the difference between the concentration of product before and after equilibrium, c^* , gives the sorbed protein mass q^* . Plotting q^* versus c^* yields the equilibrium sorption isotherm. Assuming that single-site interaction occurs between bioproduct and sorbent, and also that nonspecific interactions are absent, the apparent constant K_A and the maximum product-binding capacity q_m may be evaluated by fitting the experimental data to the well-known Langmuir model:

$$q^* = \frac{q_m \cdot K_A \cdot c^*}{1 + K_A \cdot c^*}$$

Non-Langmuirian behaviour may point to multiple interaction sites. In such cases, appropriate models may be worked out to fit the experimental data and used to determine whether this behaviour may be due to additional nonspecific interaction sites from the sorbent's surface, or to product-product interactions with the first adsorption layer.

Kinetics of Adsorption

Another important factor of sorption performance is the kinetics of the adsorption/desorption reactions. The rates of these reactions dictate the length of time that has to be allowed to attain equilibrium. For example, the adsorption of protein on to packed beds involves three processes.

First, the protein is transported from the bulk fluid to the outer surface of the adsorbent particles by film mass transport. Second, intraparticle transport occurs

by diffusion. Finally, the protein binds to ligand attached to the inner surface of the particle. It is important to determine which of these processes is the rate-limiting step.

Process Design

Isolation of bioproducts by ion exchange processes can be carried out either batchwise or by traditional packed-bed techniques. In the former, the exchanger is added to the product solution in a vessel which is mixed until sorption has occurred.

Packed-Bed Column

In a packed-bed column the movement of liquid through the bed approximates to plug flow, resulting in a maximum number of theoretical equilibrium stages within the column and hence good adsorption and chromatographic performance. The overall flow performance is strongly related to the length and shape of the ion exchange zone evolving during sorption and regeneration. This zone appears between the section of column saturated with product and the section that still contains fresh sorbent. As loading or regeneration progresses, the zone moves along the column in the direction of the liquid flow. Breakthrough occurs when the zone approaches the end of the column and the concentration in the outlet stream increases sharply. Breakthrough profiles provide a measure of the performance of different ion exchangers in packed-bed operations. A sharp breakthrough profile is desirable in order to achieve efficient use of sorbent. Figure 1 shows breakthrough profiles for two hypothetical adsorbents with identical equilibrium capacities. It can be seen that a greater proportion of bed capacity is used in the case of sharp breakthrough.

Figure 1 Hypothetical breakthrough curves for two sorbents. The unfavourable breakthrough curve (triangles) is flat and trailing, while the favourable breakthrough curve (circles) is sharp and steep.

Fluidized Bed Column

In a fluidized bed, liquid upflow through the column causes the resin particles to become separated from each other. This technology has attracted attention for biochemical separation processes because it enables direct treatment of crude feedstocks from fermentation reactors. There are two important criteria that must be met before fluidized bed sorption can be considered a viable method for separating products from unfiltered fermentation broths. First, broth solids must have a lower terminal settling velocity than the resin, and the terminal velocity of the resin must be sufficient to achieve reasonable time cycles. Terminal velocity is defined as the upflow velocity at which particles will not remain in the column. Second, the dynamic adsorptive capacity of the resin for the product must be of such a magnitude that optimal yield, purity and cycle time can be achieved.

Determining optimum resin terminal velocity and dynamic sorptive capacity for a specific product is a complex process. The breakthrough curves are usually obtained for a variety of design and operating conditions (column size, distributor, bed type, bed height, flow rate and number of stages). It is also essential to find an appropriate mathematical model for simulation and optimization of the processes. An extensive literature exists describing the mode of operation of fluidized beds with reference to bioproduct

separation. A schematic representation of fluidized bed separation is given in Figure 2.

New Developments

Although ion exchangers remain the most frequently used media for separation of biological mixtures, some novel approaches have emerged. Perfusion chromatography is one of them. This method exploits the fact that particle resins have very large pores (600–800 nm) that permit convective flow. A high surface area for sorption is provided by the presence of numerous small diffusive pores. Thus, convection rather than diffusion dominates the mass transport of the sample molecules. This makes the process 10 times faster than the usual separation process without much loss in capacity or resolution.

Another approach which has emerged as a powerful separation tool is immobilized metal affinity chromatography (IMAC). In this method, immobilized ligands, like iminodiacetic acid, produce chelates with transition metal ions (such as Ca^{2+} , Zn^{2+} and Fe^{3+}) which, when exposed to a protein, form a ternary complex on the protein surface. Further isolation is then accomplished with ease.

In conclusion, the latest developments in sorption media and separation technology provide a broad and varied basis for identification of appropriate sorbents and selection of contact mode between feedstock and sorbent.

RESTRICTED-ACCESS MEDIA: SOLID-PHASE EXTRACTION

Introduction

For the determination of drugs and their metabolites in serum or plasma by high performance liquid chromatography (HPLC), tedious and time-consuming pretreatment procedures such as liquid-liquid extraction, solid-phase extraction (SPE) or membrane-based extraction are often required. Among those pretreatment procedures, SPE is the most widely used for extraction of target compounds in biological fluids. However, direct injection of serum or plasma samples onto HPLC or SPE materials causes protein denaturation with accumulation of materials on the sorbent, resulting in undesired loss in the capacity and selectivity of the sorbent. Thus, it is essential to remove serum or plasma proteins before loading the samples onto the HPLC or SPE sorbents. Recently, restricted access media (RAM) materials were introduced for direct injection of proteinaceous samples onto the HPLC or SPE materials. With RAM materials large molecules such as proteins are eluted in the void volume without destructive accumulation because of restricted access to some surfaces, while allowing small molecules such as drugs and their metabolites to reach the hydrophobic, ion-exchange or affinity sites and be separated. One approach uses an internal-surface reversed-phase (ISRP) material, produced from porous silica gels, which has hydrophobic interior and hydrophilic exterior surfaces, as shown in Figure 1. The ISRP-GFF material (GFF = glycine-L-phenylalanine-L-phenylalanine) was prepared from covalently modified glyceryl-

propyl (i.e. diol) phases by attachment of the tripeptide GFF, bonded via the amino groups to the glycerylpropyl groups. The phenylalanine moieties were then cleaved from the external surface of the silica with carboxypeptidase A, which is too large to enter the small pores. After this enzymatic treatment, the glycerylpropyl moieties and glycine residues remain on the external surface. Because the ISRP concept was innovative for drug determinations in serum, many RAM materials were subsequently developed. Another RAM material based on silica gels is shielded hydrophobic phase (SHP), which consists of a

Figure 1 Schematic representation of an internal-surface reversed-phase (ISRP) material. Proteins do not adsorb on the hydrophilic exterior surfaces and do not penetrate into the hydrophobic interior surfaces, while analytes can reach the interior surfaces and be separated. hydrophilic polyoxyethylene network embedded with phenyl groups, bonded to both the external and internal surfaces of the particles (Figure 2). Other RAM materials based on silica gels include semipermeable surface, dual zone and mixed function phase materials.

RAM materials based on polymer beads have also been developed. For example, one polymer-based RAM material was prepared from porous uniformly sized poly(glycidyl methacrylate-co-ethylene dimethacrylate) beads. Hydrolysis of the epoxide groups to diols can be carried out exclusively within the large pores of the medium through the use of a polymeric catalyst, polystyrenesulfonic acid (average molecular weight, 141 000 Da). The epoxide groups remaining in the small pores after hydrophilization of the large pores were then reacted with either hydrophobic

C₁₈ or phenyl groups, or more polar diethylamino groups. The pore-size selective modification of porous materials provided the RAM materials as shown in Figure 3.

RAM materials could be used for direct serum injection assays of drugs as HPLC or SPE materials. The former materials have been designed and used preferentially as packings for large-size (150 × 4.6 mm i.d.), i.e. analytical columns. In this case the extraction and separation of analytes take place simultaneously. For SPE RAM, sorbents were packed into a small (typically 5–30 mm × 3–4.6 mm i.d.) precolumns connected to an analytical column via a six-port valve, i.e. switching valve. In the coupled-column mode this is a sequential process. The two approaches for the extraction and analysis of the target compounds in biological fluids by HPLC are compared in Table 1.

Single-column Mode

When using the RAM materials, the ionic strength and pH of an eluent, and the content of organic modifier are limited in order to prevent precipitation of serum proteins. For the ISRP–GFF materials, the recommended eluent pH range was 6.0–7.5. The recovery of serum proteins was low at acidic pH. This is due to the electrostatic attractions of the serum proteins having a net positive charge (isoelectric point, *pI* of serum albumin, 4.7) and the external glycine residues having a negative charge. Taking into account the *pK_a* values of the bound glycine (between 2.3 and 3.0), the recovery of serum proteins might be higher with an eluent pH below 2. However, chemically bonded columns cannot be used for long periods at this pH because of the hydrolysis of the bonded phase. However, for RAM materials such as SHP, whose external surface has no charges, there is no eluent pH limitation. These materials can be used at any pH suitable for siloxane-bonded silicas (pH 2–8). These results demonstrated that external uncharged surfaces should be suitable for the external layers of RAM materials. With regard to the eluent, an ionic strength of 0.05–0.2 was used. The preferred organic modifiers are acetonitrile, 2-propanol, tetrahydrofuran and methanol because they can afford a wide selectivity in controlling solute retention on the accessible hydrophobic surfaces. The content of the organic modifier should be < 20%.

Direct serum injection assays of drugs were carried out on the ISRP–GFF materials. The chromatograms of plasma spiked with probenecid or lidocaine at clinical levels (50 µg mL⁻¹ for probenecid, 5.94 µg mL⁻¹ for lidocaine) are shown in Figures 4 and 5, respectively, together with those for methanolic solutions of the

Detection	UV > 240 nm Fluorescence detection – yes Electrochemical detection – no	No limitation
Column lifetime	Short	Long
Cost/analysis	High	Low

same concentration. The recovery was calculated from the peak-area ratio of a given concentration of the drug dissolved in plasma and methanol. Despite the differences in the bound fractions (83–94% for probenecid and 65–77% for lidocaine), both drugs were almost completely recovered from plasma samples. The large difference in the intensities of the background peaks in these chromatograms is due to

the difference in the detection wavelengths. Naturally, the shorter wavelength (220 nm for lidocaine) reveals more matrix peaks at a higher intensity than the longer wavelength (254 nm for probenecid). In

both cases the eluent pH was about 7. However, phenytoin was not eluted under the neutral conditions on the SHP materials, but when the eluent pH was adjusted to 2.5, it was eluted and resolved from serum matrix components (Figure 6). Because of the presence of secondary amines on phenytoin, the retention factor of phenytoin was decreased by reducing the eluent pH. Since the SHP materials had no charged groups on the external surface as described above, they could be used at eluent pH 2.5.

In the above applications, less than 100 μL of serum sample was injected. At higher sample volumes, analyte peaks were broadened and a plateau peak was observed. The plateau peak is dependent on the unbound fraction of analyte. Whether the broadened or plateau peak appears; that is, when the unbound drug fraction is higher, we can inject a larger sample volume for direct serum injection assays of the drug without peak-broadening.

On the other hand, both free and total drug concentrations could be simultaneously determined by injecting such a larger sample volume that the plateau peak of a drug appears. Figure 7 shows the chromatogram of 8.00 $\mu\text{g mL}^{-1}$ carbamazepine (CBZ) in human plasma. CBZ was well separated from the blank peak and gave a clear and wide plateau. The CBZ concentration calculated from this plateau height was

1.97 $\mu\text{g mL}^{-1}$, which agreed with the free CBZ concentration determined by means of ultrafiltration (2.08 $\mu\text{g mL}^{-1}$). Furthermore, it is interesting that the CBZ concentration calculated from the area of this plateau was 8.06 $\mu\text{g mL}^{-1}$, in agreement with the total CBZ concentration of this plasma sample. This implies that both free and total drug concentrations can be determined simultaneously by a single analysis based on the height and area of the drug plateau, respectively. However, it is required to inject a large sample volume (in this case, 1.8 mL plasma sample) in order to observe the plateau peak. Further, the plateau peak cannot always be separated from blank peak, dependent on the drug separated.

Coupled-column Mode

As shown in Table 1, the advantages of a coupled-column mode include separation selectivity (ability to couple precolumns and analytical columns of different selectivity), detection sensitivity (analyte enrichment due to larger sample volumes and reduced number of interfering peaks), and higher variability of mobile phases and detection modes. In recent times RAM materials have mainly been used in the coupled-column mode.

Figure 8 shows a representative chromatogram obtained after the direct injection of an untreated human serum sample onto a RAM precolumn. The injection was followed by fully automated online extraction and subsequent separation of antiepileptic

drugs on a conventional analytical reversed-phase HPLC column. The precolumn (25 mm \times 4 mm i.d.) packed with one of ISRP materials (particle size, 25 μ m) can tolerate 2000 injections or more of 50 μ L of human plasma.

Future Trends

Since the invention of the ISRP–GFF materials, various RAM materials have been developed for direct serum injection assays of drugs with single- and coupled-column modes. However, they are lacking in selectivity because hydrophobic or ion-exchange ligands are used as the analyte binding ligands. In the future, more selective ligands such as immunoaffinity or chemoaffinity ligands or molecularly imprinted polymers have the potential to further improve selectivity and sensitivity in bioanalysis.

REVERSED-FLOW GAS CHROMATOGRAPHY

N. A. Katsanos, University of Patras, Patras, Greece

Introduction

Gas chromatography (GC) is a technique that is used not only to separate substances from each other, but also to ‘separate’ physicochemical quantities by

measuring the value of one in the presence of another, e.g. the rate of a chemical reaction in the presence of diffusion phenomena. Several books, reviews and original papers have been published dealing with physicochemical measurements by GC. Some of the properties measured pertain to the moving gas phase, e.g. diffusion coefficients of solutes into the carrier gas, and the emphasis is on determining the properties of the solutes. However, the majority of physicochemical properties studied by GC relate to the stationary phase and its interaction with well-known probe solutes, e.g. the catalytic properties of the solid stationary phase for reactions between gases. This is termed inverse gas chromatography and has the stationary phase of the system as the main object of investigation. The procedures employed are the same as those used in direct GC, but the results are used to derive properties of the stationary phase. The main source of information obtained experimentally is the broadening of the chromatographic elution peaks, mainly due to nonfulfilment of the assumptions under which the central chromatographic equation is derived, namely: (1) negligible axial diffusion of the solute gas in the chromatographic column; (2) linearity of the distribution isotherm; and (3) instantaneous equilibration of the solute between the mobile and the stationary phase. Classical chromatographic systems are not usually in true equilibrium during the retention period, so that extrapolation to infinite dilution and zero carrier gas flow rate is required to approximate true equilibrium parameters.

Another approach to extracting information about the physicochemical properties of the stationary phase from the elution peaks is based on the analysis of the statistical moments of the peaks. Both of these approaches, i.e. measurement of the broadening of the peaks and analysis of their statistical moments,

are dynamic measurements because of the convective movement of the carrier gas inside the chromatographic column. In many cases achieving an acceptable precision for the quantities determined is a difficult, if not impossible, task. The reversed-flow gas chromatography (RF-GC) technique offers an additional route from experimental measurements to the properties of the stationary phase, as described below.

Physical Description and Experimental Arrangement of the System

Although there would be no GC without a mobile gas phase, i.e. a carrier gas, in most studies its flow rate remains constant throughout a single experiment. The magnitude of the flow rate is usually treated as an adjustable parameter. There are, however, two flow rate perturbation methods, the *stopped-flow* and the *reversed-flow* techniques. Both are very simple to apply and consist of either *stopping* the carrier gas flow for short time intervals, or *reversing* the direction of its flow from time to time. Experimentally, this is easily done by using shut-off valves in the first technique and a four-port valve in the second, as shown in Figure 1. By switching the valve from the position shown by the solid lines to that indicated by the broken lines, the carrier gas, flowing initially from end D_1 to D_2 of the sampling column, now flows in the opposite direction, i.e. from D_2 to D_1 . The sampling column is a usual 1/4 in (6.35 mm) stainless-steel or glass chromatographic tube of total length $l' + l$ ranging from 40 + 40 cm to 100 + 100 cm, either straight or bent and empty of any solid or liquid material.

The system also contains two other columns: a separation column and a diffusion column.

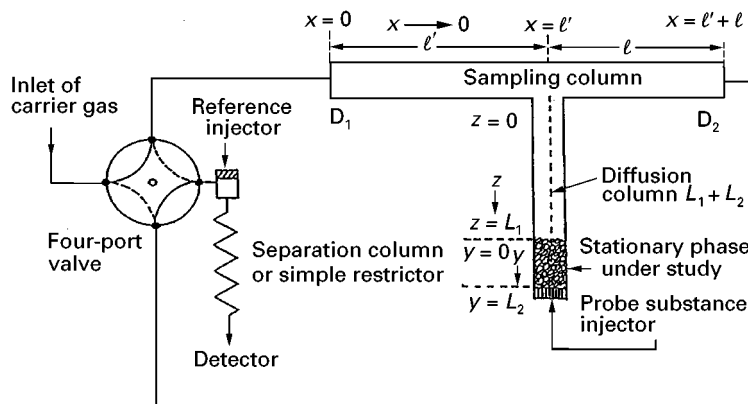

Figure 1 Schematic representation of columns and gas connections showing the principle of RF-GC. Reprinted from *Journal of Chromatography A* 775; 1997, 211–224, with permission from Elsevier Science.

A separation column of any suitable diameter and length is placed before the detector. The carrier gas flows normally in one direction through this column without any reversal, as shown by the gas connections of the valve. The separation column is filled with ordinary stationary-phase material and is used to effect the separation of two or more substances reaching the valve from the sampling column. A reference injector at the inlet end of the separation column is used for identification purposes. If only one substance reaches the detector, a simple restrictor suffices.

A diffusion column of the same diameter as the sampling column and length 30–100 cm is connected perpendicularly at about the middle of the sampling column; it is closed at the other end, and therefore no carrier gas flows through it.

The whole system of the three columns described above is placed within the oven of an ordinary gas chromatograph, with the columns and the connection tubes properly bent. The question naturally arising is: what happens when the direction of the carrier gas flowing through the sampling column is reversed, if it is not reversed in the separation column and there is no flow at all through the diffusion column? If the diffusion column does not contain any stationary phase, but only stagnant carrier gas, nothing would happen. If a probe gas is introduced through the injector into the empty diffusion column, the repeated flow reversals of duration 10–100 s would create narrow and symmetrical peaks like those shown in **Figure 2** (*sample peaks*). From the height H of these peaks in arbitrary units, measured as a function of time, t , that elapses between the injection of probe substance and the respective flow reversal, the diffusion coefficient of the substance into carrier gas can be calculated. Finally, if a certain length L_2 (3–12 cm) of the diffusion column is filled with a stationary phase, the *diffusion band* obtained by plotting H or $\ln H$ against t is different from before, owing to the interactions of this phase with the gaseous probe. This is a way of separating the pure chromatographic process from the rate or equilibrium processes involving the stationary phase.

The RF-GC method was first introduced in 1982, after preliminary studies on heterogeneous catalysis. It was later developed for measuring various physicochemical quantities pertaining to both, substances contained in the moving gas phase and stationary-phase behaviour. The technique was reviewed in 1988 and again more recently. It does not have any of the disadvantages connected with the carrier gas flow and the instrumental spreading of the chromatographic bands, because the phenomena being studied take place inside the diffusion column $L_1 + L_2$ (cf. Figure 1), with no carrier gas flowing

Figure 2 Sample peaks of propene in nitrogen carrier gas, with section L_2 (9.6 cm) containing 0.67 g TiO_2 , at 323.2 K. FID, flame ionization detector.

through it. The flow reversals are used merely as a means for repeated sampling of the concentrations at the point $x = l'$, i.e. at the exit of the section L_1 . This sample is transported to the separation column (containing another stationary phase for separation purposes only), and then to the chromatographic detector, without measuring the elution velocity of the sample peaks or the carrier gas flow rate, provided it is steady. An obvious difference between conventional elution gas chromatography and RF-GC is that in the former longitudinal gaseous diffusion currents are parallel to the chromatographic current, while in the second method diffusion is, from the outset, physically separated from the chromatography by placing the diffusion process perpendicular to the chromatographic process.

Mathematical Models

Inverse gas chromatography has been used for studying many properties of solids, such as the glass transition of polymers, their crystallinity and melting point, and the thermodynamics of their solutions. The RF-GC technique is a useful tool for inverse chromatographic studies, particularly when gas–solid interfaces are involved. Several such studies have been published. Here a short outline of its possibilities is given using some characteristic examples. Take for instance the determination of diffusion parameters, adsorption–desorption rate constants and isotherms, and catalytic rate constants of some gaseous probes on typical solid catalysts, supported or not. All these physicochemical properties can be determined simultaneously in a single gas chromatographic experiment lasting a few hours. The experiment resembles those conducted with a plug flow reactor, but without a gas flowing through it, as Figure 1 shows. It is only gaseous diffusion of the reactant(s) and product(s) that

causes the movement of these substances through the solid bed along the length coordinate y , and then along length coordinate z to the junction $x = l'$ of the sampling column. Two diffusion coefficients of the probe molecules are involved in these movements: D_1 in section L_1 and another D_2 in section L_2 influenced by the bed obstruction factor γ . These are taken care of implicitly in the mathematical analysis, without using the actual values of D_1 and D_2 from the literature.

The mass balance equation of the probe reactant A in the region y (cf. Figure 1) filled with the stationary phase under study is:

$$\frac{\partial c_y}{\partial t} = D_2 \frac{\partial^2 c_y}{\partial y^2} - k_{-1} \frac{a_s}{a_y} (c_s^* - c_s) \quad [1]$$

where c_y is the gaseous concentration of the probe A in region y ; t is the time measured from the moment of injection of A as an instantaneous pulse (delta function, δ) onto the solid bed, at $y = L_2$; k_{-1} is the rate constant for desorption of A from the bulk solid; a_s is the amount of stationary phase per unit length of solid bed; a_y is the cross-sectional area of the void space in region y ; and c_s , c_s^* are the concentrations of A adsorbed on the solid at time t and at equilibrium, respectively.

An analogous mass balance equation is valid for the gaseous concentration c_z of A in diffusion column z :

$$\frac{\partial c_z}{\partial t} = D_1 \frac{\partial^2 c_z}{\partial z^2} \quad [2]$$

It is noteworthy that the usual convective terms $-\nu(\partial c_y/\partial y)$ and $-\nu(\partial c_z/\partial z)$ of gas chromatographic mass balances (ν being the average linear velocity of the carrier gas) are missing from both the above equations, since no carrier gas flows through column sections y and z . This makes the solution of differential eqns [1] and [2] much easier, and all disadvantages connected with the carrier gas flow mentioned before disappear. No 'competition' between ν and rate processes on the gas-solid interface takes place. No corrections of ν are required, not even the measurement of its approximate value is needed, except only to calculate a calibration factor g which is needed in the isotherm determinations. Both eqns [1] and [2] have the form of Fick's second law for diffusion in one dimension, the first equation being modified only by inclusion of the far right-hand side term describing the overall rate of adsorption of the probe gas A onto the surface of the stationary phase.

The system of partial differential equations, eqns [1] and [2], is complemented by:

1. the rate of change of the adsorbed concentration c_s :

$$\frac{\partial c_s}{\partial t} = k_{-1}(c_s^* - c_s) - k_2 c_s \quad [3]$$

now including a rate constant k_2 of a possible first- or pseudofirst-order surface reaction of the adsorbed substance A; and

2. a local experimental adsorption isotherm:

$$c_s^* = \frac{n_s}{a_s} \delta(y - L_2) + \frac{a_y}{a_s} k_1 \int_0^t c_y(\tau) d\tau \quad [4]$$

where n_s is the initially adsorbed amount of A, k_1 is a dynamic adsorption rate constant, and τ is a dummy variable for the time t . The adsorption equilibrium is local and instantaneous, the adsorption parameter k_1 transforming the area under the c_y versus t curve into c_s^* .

Equation [4] describes the actual experimental isotherm, not necessarily a linear one, without the help of an *a priori* isotherm equation (Langmuir, BET, etc.). The graphical experimental isotherm can be constructed in detail if desired, but this is not necessary. Only the basic definition by eqn [4] suffices to incorporate the exact isotherm into the mathematical calculations. The nonlinearity in general is automatically taken into account.

The use of a dummy variable τ for the time t simply facilitates the notation in the integral of eqn [4] without any special meaning attached to τ .

The system of eqns [1]–[4] is solved under the initial conditions:

$$c_z(0, z) = 0, \quad c_y(0, y) = \frac{n_A}{a_y} \delta(y - L_2)$$

and:

$$c_s(0, y) = 0 \quad [5]$$

where n_A is the total amount of A injected. The solution is effected by using double Laplace transforms of all terms with respect to time and length coordinates, under the given initial conditions and the isotherm eqn [4], and subject to the appropriate boundary conditions at $z = 0$, $z = L_1$ and $y = L_2$. By means of various approximations this leads to the expression:

$$H^{1/M} = g c_z(0, t) = A_1 \exp(B_1 t) + A_2 \exp(B_2 t) + A_3 \exp(B_3 t) + A_4 \exp(B_4 t) \quad [6]$$

where H is the height (in arbitrary units, say cm) of sample peaks measured from the ending baseline of the chromatogram, like that of Figure 2, M is the response factor of the detector ($M = 1$ for the FID), and g is a calibration constant for the detector, transforming cm of H to mol cm^{-3} of the concentration $c_z(0, t)$ of probe substance A at $z = 0$ and time t .

A steady-state approximation for c_s in eqn [3], $dc_s/dt = 0$, leads to:

$$H^{1/M} = gc_z(0, t) = A_5 \exp(B_5 t) + A_6 \exp(B_6 t) + A_7 \exp(B_7 t) \quad [7]$$

instead of eqn [6].

The detailed assumptions on which the derivation of eqns [6] and [7] was based have been published (see Further Reading).

It is seen from eqns [6] and [7] that $c_z(0, t)$, i.e. the gaseous concentration of the probe A at the point $z = 0$ of the diffusion column (cf. Figure 1), as measured by H , should be fitted to the sum of four or three exponential functions of time. This can be achieved by a nonlinear least-squares PC program in the *Journal of Chromatography A* (1998) papers listed in the Further Reading, by entering the pairs H (peak height), t (time of reversal) in the DATA lines. The exponential coefficients of time B_1, B_2, B_3 and B_4 of eqn [6] and B_5, B_6 and B_7 of eqn [7], are calculated, together with the respective pre-exponential factors A_1, A_2, A_3 and A_4 of eqn [6], and A_5, A_6 and A_7 of eqn [7]. This PC program is based on the so-called exponential stripping method of Sedman and Wagner. The calculation of the B_i and A_i values ($i = 1, 2, \dots, 7$) is guided by the overall goodness of fit expressed by the square of the correlation coefficient r^2 . This universally accepted criterion, calculated and printed, is in the range 0.990–0.999 in most cases, showing a remarkable goodness of fit for a nonlinear regression analysis. A 't' test of significance for the smallest r^2 usually found shows that it is highly significant, with a probability smaller than 0.05% of being exceeded. The program also prints, together with the B values, their standard errors, which are usually reasonable for physicochemical measurements.

The question naturally arises as to the meaning and physical content of the parameters A_i and B_i so determined. These are given directly and explicitly by the solution of the system of eqns [1]–[5] that led to eqns [6] and [7]. They are written below:

$$\alpha_2(1 + V_1) + k_{-1} + k_2 = -(B_1 + B_2 + B_3 + B_4) = X \quad [8]$$

$$\begin{aligned} \alpha_2(1 + V_1)(k_{-1} + k_2) + \alpha_1\alpha_2 + k_1k_{-1} \\ = B_1B_2 + B_1B_3 + B_1B_4 + B_2B_3 + B_2B_4 + B_3B_4 = Y \end{aligned} \quad [9]$$

$$\begin{aligned} \alpha_1\alpha_2(k_{-1} + k_2) + \alpha_2V_1k_1k_{-1} + k_1k_{-1}k_2 \\ = -(B_1B_2B_3 + B_1B_2B_4 + B_1B_3B_4 + B_2B_3B_4) = Z \end{aligned} \quad [10]$$

$$\alpha_2V_1k_1k_{-1}k_2 = B_1B_2B_3B_4 = W \quad [11]$$

$$\alpha_2(1 + V_1) = -(B_5 + B_6 + B_7) = X_1 \quad [12]$$

$$\alpha_1\alpha_2 + \frac{k_1k_{-1}k_2}{k_{-1} + k_2} = B_5B_6 + B_5B_7 + B_6B_7 = Y_1 \quad [13]$$

$$\frac{\alpha_2V_1k_1k_{-1}k_2}{k_{-1} + k_2} = -(B_5B_6B_7) = Z_1 \quad [14]$$

$$\alpha_1 = 2D_1/L_1^2, \quad \alpha_2 = 2D_2/L_2^2,$$

$$V_1 = 2V_G(\text{empty})\varepsilon/V_G + L_2^2/L_1^2 \quad [15]$$

where V_G and V'_G are the gaseous volumes of the void spaces in regions z and y , respectively and ε the external porosity of the solid bed. The X, Y, Z, W, X_1, Y_1 and Z_1 are just auxiliary parameters to facilitate the calculation of the primary kinetic parameters k_1, k_{-1} and k_2 from B_i . This is done as follows: the sum $k_{-1} + k_2$ is obtained from the difference $X - X_1$, from the ratio W/Z_1 , or as a mean value of these two. Subtraction of $k_{-1} + k_2$ from X gives the value of $\alpha_2(1 + V_1)$. From this, α_2V_1 is easily computed since V_1 is given by the relation [15]. The calculation of k_1k_{-1} follows from the relation:

$$\begin{aligned} k_1k_{-1} = \left\{ Y - \alpha_2(1 + V_1)(k_{-1} + k_2) - \frac{Z}{k_{-1} + k_2} \right. \\ \left. + \frac{W}{\alpha_2V_1(k_{-1} + k_2)} \right\} / \left(1 - \frac{\alpha_2V_1}{k_{-1} + k_2} \right) \end{aligned} \quad [16]$$

Then, dividing W by α_2V_1 and by k_1k_{-1} gives the value of k_2 . The value of k_{-1} follows from the difference $(k_{-1} + k_2) - k_2$, and that of k_1 from the ratio k_1k_{-1}/k_{-1} .

The pre-exponential factors A_1, A_2, A_3 and A_4 of eqn [6] and A_5, A_6 and A_7 of eqn [7] are explicit functions of $gm\alpha_1\alpha_2/\dot{V}$, where \dot{V} is the volumetric flow rate of the carrier gas, and of $B_1, B_2, B_3, B_4, k_{-1}, k_2, m$ and m_s , but the analytical form of this dependence is not required in the calculations.

It is well known that the values of the three rate constants k_1, k_{-1} and k_2 , especially determined at various temperatures, are of primary importance in characterizing solid adsorbents and catalysts. The experimental data, i.e. the H, t pairs from the chromatogram, can be analysed by using a linear adsorption isotherm, instead of the real experimental isotherm (eqn [4]) without bothering whether it is linear or nonlinear. Both methods lead to the

simultaneous determination of three primary kinetic parameters, namely, k_1 , k_{-1} and k_2 . From these primary rate constants, the method based on the linear isotherm calculates the overall mass transfer coefficients K_G and K_S for the gaseous and the solid phases, respectively, while the real isotherm method computes also the deposition velocity V_d and the overall reaction probability γ of the solute with the stationary phase, by means of the relations:

$$V_d = \frac{k_1 V_G(\text{empty}) \varepsilon}{A_s} \times \frac{k_2}{k_{-1} + k_2} \quad [17]$$

$$\frac{1}{\gamma} = \left(\frac{R_g T}{2\pi M_B} \right)^{1/2} \times \frac{1}{V_d} + \frac{1}{2} \quad [18]$$

where R_g is the ideal gas constant, T the absolute temperature, A_s the total surface area of the solid, and M_B the molar mass of the probe gas. The original definition of V_d was the flux of gas to the solid surface divided by the concentration difference between the bulk gas-phase and the surface. The values of k_1 , k_{-1} , k_2 , V_d and γ are calculated and printed directly by running the PC program mentioned before.

It is clear from the definitions of V_d and γ that both parameters are independent of molecular diffusion,

being related only to the local adsorption isotherm (k_1), the desorption rate constant (k_{-1}) and the surface reaction rate constant (k_2).

The only physicochemical assumptions made concerning the gas-solid interactions are that all parameters measured directly or calculated indirectly refer to elementary steps at equilibrium. Thus the ratio k_1/k_{-1} represents the equilibrium distribution constant K , according to the principle of microscopic reversibility. Note that it is not easy to measure simultaneously rate constants of adsorption (k_1) and desorption (k_{-1}) at a dynamic equilibrium state like that justified experimentally in the experiments described here.

Finally, the explicit calculation of the isotherms has been described in the literature. However, eqn [6] provides an easy route to the calculation of the distribution of surface adsorption energies, ε , the local monolayer capacities, i.e. the maximum adsorbed concentrations, c_{\max}^* , of the probe substance on each kind i of adsorption sites, and the local adsorption isotherms $\theta_i(p, T, \varepsilon)$ on heterogeneous surfaces of solids. Many papers and books have recently been published on this subject. From c_{\max}^* , in mol per g of adsorbent, multiplying by the Avogadro number N_A and the cross-sectional area of the probe molecules in m^2 , one can find the specific surface area of the stationary phase in $\text{m}^2 \text{g}^{-1}$.

Some Representative Results

Applying the previous theoretical analysis for the characterization of some metal oxides used as solid catalysts gave the values of the physicochemical parameters k_1 , k_{-1} , k_2 , K_G , V_d and γ for five probe hydrocarbons. These are given in Table 1, calculated for both the linear and nonlinear isotherm models. It is seen that the values of some physicochemical parameters are significantly different for the two models; it is clear that for an inorganic solid of the kind used as a catalyst the linear isotherm model is inadequate, due to the nonuniformity of the surface. The two physicochemical parameters k_1 and k_{-1} characterize any newly prepared catalyst. These constants can be measured easily and accurately and their values supply a reliable catalyst characterization.

An *a priori* acceptance of an adsorption isotherm equation is not needed, which is preferred to the Langmuir or the BET isotherms for this purpose. Any new catalyst sample can be tested by measuring adsorption and desorption rate constants before utilization. From Table 1, it can be seen that many values obtained from the nonlinear isotherm model are 1–4 orders of magnitude different from those corresponding to the linear model. All physicochemical quantities based on the nonlinear model are intended to characterize newly prepared catalysts, on the basis of accurately defined physicochemical concepts.

In some cases in Table 1 the ratios of the same parameters determined with linear and nonlinear isotherms are inverted in going from one gas–solid system to another. This is probably due to the fact that solid surfaces are very heterogeneous as regards adsorption energy distribution and this heterogeneity may differ greatly from one solid to another for the same hydrocarbon, and from one hydrocarbon to another for the same solid. The local adsorption isotherm of eqn [4] is very sensitive to the energy distribution function on the surface, whereas simple overall linear isotherms are not.

Of course, it is not possible from the measurements at one temperature to conclude whether the gas–solid interactions represent physical adsorption or chemisorption. Experiments at various temperatures, however, will give heats of adsorption and activation energies, from which it may be possible to draw conclusions about the nature of the adsorption processes.

Conclusion

The RF-GC technique is a useful tool in inverse GC studies. It has also some advantages for adsorption isotherm determinations in that: (1) the gaseous diffusion and resistance to mass transfer are not neglected, (2) the sorption effect in dynamic chromatographic systems is nonexistent, (3) the pressure gradient is negligible along the solid bed, and (4) the experimental isotherm can be determined in the presence of a surface reaction of the adsorbate. This is very important when dealing with catalysts, when many determinations based on chemisorption must follow every catalyst preparation.

The method briefly outlined here has been used for several published physicochemical measurements. Results have also been obtained for deposition parameters of air pollutants on solid surfaces with a simultaneous determination of the apparent rate constant of gaseous reactions above the solid, and also for the measurement of various rate coefficients and equilibrium constant by utilizing the solid phase as an internal wall coating of denuder tubes in place of the diffusion column.

RIBONUCLEIC ACIDS: CAPILLARY ELECTROPHORESIS

J. Skeidsvoll, University of Bergen, Bergen, Norway

Copyright © 2000 Academic Press

Introduction

With the introduction of capillary electrophoresis (CE), a new generation of electrophoretic techniques has seen the light of day. The scientific literature today describes a large number of applications of this powerful analytical technique in the analysis of nucleic acids. For nucleic acids, as for most other analytes, CE offers significant advantages over many of the conventional electrophoretic techniques. In general, CE is characterized by short analysis time, high resolution, accuracy and reproducibility, quantitative online detection and automation. The small sample volumes required and the extreme sensitivity CE offers, represent a large analytical potential for samples of biological origin. The fundamental analytical and operational parameters for the separation of nucleic acids by CE were identified around 1990. A decade later, CE is considered a fully developed technology for the analysis of DNA. The rapid development of this application of CE seems to have been driven by the many practical applications of electrophoretic separation and detection of DNA in both basic and applied science.

The first reported analysis of RNA by CE was published in 1993 by Reyes-Engel *et al.* and describes the separation and quantification of a specific messenger RNA by capillary zone electrophoresis. To date, only a limited number of articles have been published which focus on the application of CE in the analysis of RNA. The reason for this is not obvious, considering the widespread use of conventional gel electrophoresis of RNA throughout the biomedical scientific field. The fact that RNA, in many respects, displays similar characteristics as DNA, should constitute the basis for significant efforts in the development of RNA analyses based on CE. However, the scientific literature holds promise for a substantial increase in the use of CE in RNA analyses. The following sections intend to give a basic introduction to CE of RNA, with emphasis on important analytical and operational parameters in the analyses. Finally, examples from a diverse group of applications are presented.

Capillary Electrophoresis of RNA

In general, electrophoretic separation of RNA is based on the differences in electrophoretic mobilities of the analytes. As in conventional electrophoresis, the rate of migration of a RNA molecule in CE depends on the mass and the dimensions of the molecule, the charge carried, the applied current and the resistance of the medium. In an electric field, at moderate pH, negatively charged RNA migrates toward the anode. A number of parameters affect the separation of RNA in CE (see below). CE of RNA can be divided into two separate categories based on the principle by which the molecules are separated: capillary zone electrophoresis (CZE) and capillary gel electrophoresis (CGE). In CZE, the RNA molecules are mainly separated by their charge to mass ratio. From the fact that nucleic acids larger than a few nucleotide units have approximately identical charge to mass ratio, CZE provides little or no separation power. Consequently, only single RNA species can be identified by this technique, unless multiple labelling is being used. In CGE, the RNA molecules are separated mainly by their molecular dimensions, i.e., the ability of the different analytes to migrate through a gel matrix. CGE is by far the most common technique for RNA analyses. A description of CGE of RNA is given in the following section.

Capillary Gel Electrophoresis of RNA

Analytical parameters of significance for the separation of DNA by CGE, including gel polymer concentration, electrical field strength and temperature, have been investigated and optimized for the analysis of RNA molecules ranging from oligomers (10 to 40 bases) to several kilobases (Figure 1).

RNA Migration in Capillary Gel Electrophoresis

In conventional gel electrophoresis, the migration of a RNA molecule is inversely related to the \log_{10} molecular mass. However, base composition (primary structure) and secondary structure can affect this relationship. In CGE, separation is achieved because large molecules move more slowly through the gel than small molecules. Separation within a given RNA molecular range is obtained by selecting a gel of

Figure 1 Electropherogram of RNA molecular-mass marker. The sample was denatured, injected at 300 V cm^{-1} for 10 s and subjected to CGE at 200 V cm^{-1} in $1 \times \text{TBE}/8 \text{ mol L}^{-1}$ urea containing 0.3% HPMC. AU, arbitrary units. (Reprinted from Skeidsvoll J and Ueland PM (1996) Analysis of RNA by capillary electrophoresis. *Electrophoresis* 17: 1512–1517. Copyright 1996, with permission from Wiley-VCH Verlag GmbH.)

appropriate pore size. Experiments have demonstrated that CGE of higher molecular mass RNA (in the range from 100 bases to more than 6 kb) to a large extent resembles CGE of single-stranded DNA. An interesting finding is that RNA

Figure 2 Comparison of migration of RNA and single-stranded DNA. A molecular-mass marker containing RNA and DNA components was denatured by pre-incubation at 95°C for 3 min in the presence of 80% formamide and subjected to electrophoresis in a separation buffer containing 8 mol L^{-1} urea and 0.3% HPMC. Migration time is plotted versus molecular mass for RNA (\circ) and DNA (\bullet). (Reprinted from Skeidsvoll J and Ueland PM (1996) Analysis of RNA by capillary electrophoresis. *Electrophoresis* 17: 1512–1517. Copyright 1996, with permission from Wiley-VCH Verlag GmbH.)

and single-stranded DNA of identical length display different migration when co-analysed under completely denaturing conditions, DNA having a slightly higher migration rate than RNA (Figure 2). The shift in migration for DNA vs. RNA is found constant for molecules ranging from 100 to approximately 1000 bases. The phenomenon is explained by the higher charge to mass ratio of single-stranded DNA.

An inherent property of the (single-stranded) RNA molecule is the potential to form secondary structures or intramolecular and intermolecular hydrogen bonds. To what extent the reaction takes place is primarily a function of the RNA sequence. The predictable determination of RNA molecular mass is essential in most RNA techniques based on electrophoretic separation. Consequently, in order to prevent unpredictable migration of RNA due to the formation of secondary structures, CE should be carried out under completely denaturing conditions. Such conditions can be accomplished through optimization of physical and/or chemical parameters. For example, heating the sample in the presence of a denaturant prior to electrophoresis and addition of a denaturant in the electrophoresis and separation buffers combined with high temperature during electrophoresis should have a strong denaturing effect. Denaturants are chemical compounds that disrupt hydrogen bonds. The most commonly used denaturant, urea, is often added to the separation buffer in very high concentrations (up to 8 mol L^{-1}). Despite an extensive use of buffer additives, data from both conventional RNA gel electrophoresis and CE of RNA indicate that even the presence of 8 mol L^{-1} urea in the separation buffer is not sufficient to completely disrupt intramolecular or intermolecular hydrogen bonds. Addition of the stronger denaturant formamide in concentrations up to 30% (in addition to 3.5 mol L^{-1} urea) and performing CE at 60°C has been necessary to disrupt extensive secondary structures in a hammerhead ribozyme (37 nucleotides) and to provide appropriate separation from its substrate (17 nucleotides). In addition, a decrease in ionic (cationic) strength and an increase in pH are known to have a denaturing effect on RNA. Common problems related to inefficient separation, detection and identification of RNA in CE, probably result from incomplete denaturation of RNA.

Important Analytical and Operational Parameters

From the comprehensive scientific literature describing CE of nucleic acids, it is obvious that operational parameters like capillary dimensions (m) electrical field

strength (E , $V\text{ cm}^{-1}$) and temperature (t , $^{\circ}\text{C}$) have to be chosen carefully to optimize the separation of RNA.

In most applications of CE in RNA analyses, the electroosmotic flow is eliminated through the use of surface-modified (coated) capillaries. This considerably simplifies the experimental design and leaves the scientist with a limited number of variable analytical and operational parameters.

Buffer Composition

In general, all buffer systems that are used for CZE can also be used for CGE. The most common buffers are the Tris-borate buffers (i.e., TBE) with a pH range of 7.5–9.0. Buffer additives like methanol and acetonitrile are used in separation buffers optimized for low-molecular-mass RNA. Urea and formamide are mainly added as denaturants. Moreover, the addition of urea to the separation buffer has been found to increase the resolution of RNA (except for oligoribonucleotides less than 5 bases).

Gel-forming Polymers

A number of different gel-forming polymers have successfully been used in both DNA and RNA separations by CE. The separation matrices comprise both cross-linked gel polymers like polyacrylamide and noncross-linked gel polymers like linear polyacrylamide and cellulose derivatives. Through the optimization of composition and concentration, noncross-linked polymers have now taken over as the predominant separation matrices for most RNA analyses. These materials have demonstrated significant advantages over cross-linked polymers, including ease of preparation and use, physical stability and uncomplicated washing and refilling procedures between analyses. The resolving power of these gels mainly depends on the concentration of the dissolved polymer – dilute gels are used for high-molecular-mass RNA molecules and more concentrated gels for low-molecular-mass RNA.

A systematic study of the electrophoretic separation of RNA at different concentrations of a noncross-linked polymer gel demonstrated that high concentrations ($>0.3\%$) hydroxypropylmethylcellulose (HPMC) were optimal for the separation of RNA less than 1000 bases and low concentrations were optimal for the separation of higher molecular-mass RNA. The results are consistent with data from the separation of DNA by CE.

A number of separation matrices, optimized for different ranges of RNA molecular mass, are commercially available. Additionally, matrices are available which contain denaturants.

Electrical Field Strength

Electrical field strength is recognized as an important operational parameter in CE of RNA. An increase in electrical field strength is found to result in a logarithmic decline in migration times. Efficiency, N (number of theoretical plates) and resolution, R_s , are found to have a more complex relation to the electrical field strength, although a clear tendency towards a decline in both parameters with increased electrical field strength has been demonstrated. In general, low electrical field strengths are preferable for the optimal separation of RNA molecules larger than 100 bases. With the increase in electrical field strength, an increased current will result in the production of heat (Joule heating), which, if excessive, adversely affects the separation by causing broadening of the migrating zones.

Temperature

Temperature, an important analytical and operational parameter, influences both total analysis time and system efficiency. The effect is mainly mediated by a decrease in the separation buffer viscosity. A linear decrease in migration time for RNA molecules ranging from 200 to 2000 bases has been observed for temperatures ranging from 20 to 50°C . The separation efficiency and resolution were found essentially constant over the temperature range. In addition, temperature is a parameter of significant importance in the CE of RNA due to its denaturing effect on intra- and intermolecular hydrogen bonds.

Quantitative Aspects

For a general description of the quantitative aspects of injection in CE, see 'DNA: Capillary Electrophoresis'. Electrokinetic injection is the most common injection mode for RNA in CE. In order to obtain quantitative data, an external reference should be added to or co-injected with the RNA sample. Ideally, the external reference should resemble the sample of interest, but be readily identifiable. Hydrodynamic injection is often used in experiments for the determination of reaction kinetics or in studies of enzymatic activity. Hydrodynamic injection provides representative samples for analysis.

UV absorbance is the most common detection principle for RNA in CE. Despite its general usefulness, the technique suffers from low sensitivity as compared to other detection principles (e.g., laser-induced fluorescence) and represents a limiting factor in some RNA analyses. Detection of RNA based on (laser-induced) fluorescence confers the selectivity

and sensitivity required for a number of analyses where the concentration of analytes is low. However, this detection principle normally requires the covalent attachment of fluorophores to target molecule(s) or fluorogenic buffer additives.

Applications

The application of CE to RNA includes a diverse group of analyses, which often includes one or a combination of the following elements:

- Characterization of RNA molecular dimensions (mass or spatial structure).
- Characterization of RNA sequence.
- Characterization of RNA reaction kinetics.
- Characterization of RNA-binding constants.

An example of a group of CE-based RNA analyses that combines more than one of these elements is the hybridization techniques, which both rely on molecular mass determination and sequence-specific detection of the RNA of interest. In the applications described, RNA samples originate either from chemical synthesis (oligoribonucleotides) or are extracted from biological material. The last group comprise RNA of eukaryotic, prokaryotic and viral origin.

Characterization of RNA Molecular Dimensions (Mass or Spatial Structure)

Capillary electrophoresis analysis of synthetic short-chain oligoribonucleotides (Figure 3) Thirty synthetic oligoribonucleotides, ranging from 3 to 18 nucleotides were analysed by CE in a nondenaturing noncross-linked gel polymer. An equation was developed, based on the experimental data which, under fixed conditions, accounts for the influence of charge to mass ratio (i.e., net charge and base composition) on migration time. High resolution (1 nucleotide unit) was

obtained for homologous series of oligoribonucleotides, and, to some extent, for groups of oligoribonucleotides of identical length, but different sequence.

CGE is often used to determine the quality of chemically synthesized oligoribonucleotides and can be used in conjunction with HPLC to develop an effective method for the purification of crude oligonucleotide solutions.

Low-molecular-mass RNA fingerprinting of bacteria by capillary electrophoresis RNA profiling provides a direct genotypic fingerprint technique for the identification and classification of bacteria by generating an electropherogram including three groups of molecules of taxonomic significance, small tRNAs, large tRNAs, and 5S rRNA (ranging from 70 to 135 nucleotides). The technique is of particular importance for molecular ecology and taxonomic studies, and can also be applied directly to analyses of environmental samples. CGE using both noncross-linked polymer gels (HPMC) and cross-linked polyacrylamide gels have been investigated and optimized for their applicability in the separation of this class of RNA molecules. Good resolution was obtained only for small tRNAs up to approximately 80 nucleotides using cross-linked gels, larger tRNAs and 5S rRNA could not be resolved with this experimental set-up. The use of noncross-linked polymer gels resolved tRNAs and 5S rRNA under nondenaturing conditions, even when they possessed only different secondary structure or small differences in length (1–5 nucleotides). CE using HPMC in the separation buffer resulted in both good peak resolution and reproducibility and was suitable for routine fingerprinting of bacterial low-molecular-mass RNA.

Investigation of intracellular metabolism of a stabilized ribozyme by CGE after uptake by transfection or as free ribozyme CGE has been used to investigate

Figure 3 CGE analysis of a mixture of 12 oligoribonucleotides from 4 to 18 units under nondenaturing conditions. (Reprinted from Kolesar JM, Allen PG and Doran CM (1997) Direct quantification of HIV-1 RNA by capillary electrophoresis with laser-induced fluorescence. *Electrophoresis* 697: 189–194. Copyright 1997, with permission from Elsevier Science.)

cellular uptake and degradation of a fluorescein labeled chemically stabilized ribozyme (37-mer). After internalization by transfection or uptake of free ribozyme, electrophoretic peaks of intact ribozyme and different degradation products were easily resolved and the amount of intracellular intact ribozyme quantified. Using laser-induced fluorescence for detection, the method offered extreme sensitivity with estimated limit of detection: 10 and 200 pmol L⁻¹ ribozyme from cell extracts and cell medium, respectively.

A third example include the direct quantification (by UV absorbance measurements) of HIV-1 RNA in human plasma by CZE.

Characterization of RNA Sequence

An important and diverse group of analytical RNA techniques is based on sequence-specific hybridization between two single-stranded nucleic acids and the electrophoretic separation, detection and quantification of the intermolecular reaction product (hybrid). Consequently, the analyses involves characterization of RNA in two dimensions, size and sequence. The Northern (RNA) blotting technique, the nuclease- (S1 or RNase) protection assays and other RNA-hybridization techniques play an important role in the qualitative and quantitative analysis of all classes of RNA in biological systems. The techniques often involve use of radioisotope labels in detection.

CE-based hybridization analyses of RNA has been successfully demonstrated for a number of applications. In general, the hybridization reactions are carried out pre-column (in solution) and the separation and detection of the hybrids on-column. It is demanding to transfer the conventional hybridization techniques to the capillary format and important challenges are related to the development of selective and compatible conditions for both the pre-column and on-column elements of the analyses. Additionally, the low sample volumes injected in CE represent significant analytical and instrumental challenges.

Direct quantification of a specific messenger RNA by capillary zone electrophoresis Total RNA was isolated from whole blood and hybridized with a biotinylated oligonucleotide specific for a receptor mRNA (angiotensin II). The hybrid was first captured on streptavidin-conjugated magnetic beads, then eluted and finally quantified by UV absorbance in CZE. Using this procedure, quantification of the expression of low expressed genes is easy and fast and subject to two limiting factors: the specificity of the capturing oligonucleotide or probe selected and the amount of total RNA. The procedure represents an nonradioactive alternative to conventional RNA ana-

lyses like Northern blotting, RT-PCR or the nuclease- (S1 or RNase) protection assays.

Direct quantification of HIV-1 RNA by capillary electrophoresis with laser-induced fluorescence (LIF) detection (Figure 4) A hybridization method using a HIV-specific probe with analysis by CE-LIF was developed. Plasma samples from HIV-seropositive patients were lysed to obtain RNA, hybridized with a fluorescein-labelled HIV-specific DNA probe, digested by a specific RNase to remove nonhybridized RNA and analysed by CE-LIF in presence of the fluorescent intercalator thiazole orange (TO). 19 fg (corresponding to 1710 copies per mL of starting plasma) of HIV RNA was quantitatively detected. The technique, analogous to the conventional RNase protection assay, takes advantage of signal amplification by using the RNA-binding fluorescent intercalator TO. Calibration is done through the analysis of a fluorescein-labelled RNA marker. The actual approach appears to be an efficient, sensitive and reliable method to specifically and quantitatively analyse RNA from a variety of sources.

Detection of oligonucleotide N3'-P5' phosphoramidate/RNA duplexes with capillary gel electrophoresis The DNA analogues N3'-P5' phosphoramidates (3'-phosphoramidates) has demonstrated favourable properties as hybridization probes, including high melting temperature of duplexes with RNA and high reaction rate at low ionic strengths. The RNA hybridization technique takes advantage of the 3'-phosphoramidate oligomer properties as hybridization probes through duplex formation with short complementary strands of RNA of identical length (9 nucleotides). Hybrids were found to have unique relative mobilities in CGE, compared to the reactants. The ability of CGE to detect the presence of, and to discriminate between, perfect duplexes and duplexes that contained a base mismatch were demonstrated under routine electrophoretic running conditions. In conclusion, the study indicates that 3'-phosphoramidate oligonucleotides may have application in nucleic acid based diagnostics.

Characterization of RNA Reaction Kinetics

Current commercial CE instrumentation offers the scientist operational functions like thermostated sample compartments, automatic sampling and thermostated analyses. These functions increase the potential of CE technique developments, compared with most conventional gel electrophoresis systems, and are especially useful in studies of reaction kinetics, for the determination of association and dissociation constants and in enzymatic assays.

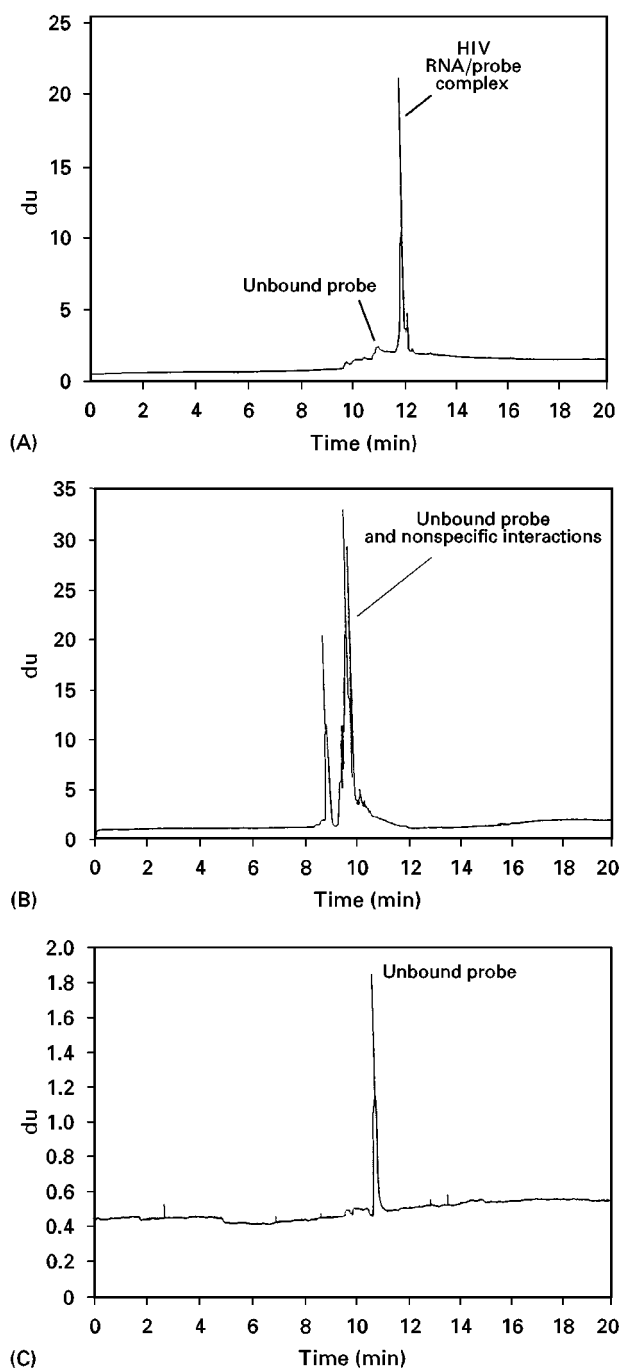

Figure 4 Electropherogram from a hybridization experiment. RNA samples obtained from a HIV-seropositive patient and a seronegative volunteer were hybridized with a HIV-specific probe and analysed by CGE: (A) HIV RNA/probe complex (HIV-positive patient); (B) seronegative volunteer; (C) negative control containing all reaction components except RNA. (Reprinted from Kolesar JM, Allen PG and Doran CM (1997) Direct quantification of HIV-1 RNA by capillary electrophoresis with laser-induced fluorescence, *Journal of Chromatography B* 697: 189–194. Copyright 1997, with permission from Elsevier Science.)

A thermostated and closed sample vial and a computer-controlled injection system is equivalent to a chemical reaction chamber and an automatic

sampling operation, respectively. CE has developed into an effective technique, for example, determination of apparent equilibrium constants for molecular association in solution. Examples of CE being used in the characterization of RNA reaction kinetics are described below.

Determination of the catalytic activity of a hammerhead ribozyme (Figure 5) Ribozymes are sequences of catalytic RNA. The catalytic activity of a synthetic hammerhead ribozyme (37-mer), i.e., the hydrolysis of its RNA substrate (17-mer), has been determined by regular injection from the reaction vial. Kinetic parameters like k_m and k_{cat} were calculated from the integrated area of the decreasing substrate peak. Experimental conditions compatible with both ribozyme activity and CE separation of ribozyme and substrate were determined by careful optimization of the reaction mixture (sample) and the separation buffer. A combination of thermal and chemical denaturation was necessary to separate the oligoribonucleotides. Kinetic analyses were performed in the range where

Figure 5 Typical electropherograms demonstrating different stages in a ribozyme-mediated catalytic breakdown of a RNA oligonucleotides substrate. (Reprinted from Saevens J, Schepdael AV and Hoogmartens J (1999) Capillary electrophoresis of RNA oligonucleotides: catalytic activity of a hammerhead ribozyme. *Analytical Biochemistry* 266: 93–101. Copyright 1999, with permission from Academic Press.)

the substrate exhibited linear detector response. RNA detection by UV absorbance was found to be a limiting factor in the Michaelis–Menten analysis.

Characterization of pre-tRNA maturation by RNase using capillary gel electrophoresis A CGE-based technique has been developed in order to characterize the reaction kinetics and mechanism for maturation of a set of pre-tRNA^{fMet} mutants. At all steps of the study of RNase P, including the preparation of the pre-tRNA (quality), the kinetic analysis and the control and yield of the purification steps, CGE was found appropriate and reliable.

Analysis of a ribonuclease H digestion of N3'–P5' phosphoramidate–RNA duplexes by capillary gel electrophoresis The activity of a ribonuclease H (RNase H)-mediated RNA hydrolysis of duplexes formed by oligodeoxyribonucleotides or their analogue, N3'–P5' phosphoramidates and complementary RNA strands, have been investigated. The enzymatic assay conditions were carefully optimized enabling sampling directly from the reaction mixture. CGE electropherograms revealed that RNA–N3'–P5' phosphoramidates duplexes remained intact and therefore did not appear to be a substrate for RNase H.

Conclusion

Today, CE of nucleic acids has become an important analytical technique for biochemists and molecular

biologists and the scientific studies described here clearly illustrate the applicability of CE in the analysis of RNA. Through efficient separations of RNA molecules ranging from a few bases to several kilobases, the specific and sensitive detection of RNA sequences and the study of RNA reaction kinetics, scientists have taken advantage of the prominent characteristics of CE. Compared to the analysis of DNA, additional challenges exist in the analysis of RNA, challenges mainly related to RNA stability and conformation. However, efforts should be made to overcome problems related to inefficient separation, identification and detection of RNA in CE. Extended insight into these phenomena will realize the inherent potential of CE for a diversity of RNA analyses.

SELECTIVITY OF IMPRINTED POLYMERS: AFFINITY SEPARATION

O. Ramström, ISIS – Université Louis Pasteur, Strasbourg, France

Copyright © 2000 Academic Press

Ever since the discovery of antibodies and receptors, and their remarkable selectivities for almost any given chemical structure, scientists have been intrigued by the quest of mimicking their properties in synthetic or

semisynthetic systems. A material carrying a selective preference for one ligand in comparison with other structurally similar compounds would be of outstanding use in a wide variety of situations, extending from molecular transportation, via analysis, to catalysis and synthesis. A multitude of sophisticated approaches have also been developed over the years, with the objective of controlling ligand binding to an artificial receptor.

Molecular imprinting technology (MIT) is an emerging concept that meets the objective of creating substrate selective materials in a fairly simple, yet efficient, manner. This technique is based on the formation of binding sites, or 'imprints', in a macromolecular matrix, or other suitable molecular support, by a molecular casting procedure. The ligand of interest is thus acting as an active guide, positioning the formation of the binding site, and the outcome is a two- or three-dimensional network embracing the template. Using dynamic interactions between the ligand (or its substitute) and selected building blocks, materials carrying a memory of the ligand structure can be formed. Once the formation of the network is established, the ligand can be removed, thus exposing the binding sites, which are subsequently accessible for repeated binding. A more general description of the molecular imprinting concept is presented elsewhere in this Encyclopedia.

The ligand affinities that can be obtained by this concept are quite remarkable and are often very similar to what can be achieved by the natural systems they are mimicking. Binding constants in the nanomolar range have been reported. Likewise, the selectivities they display are conspicuous, such that very small differences in ligand structure can be distinguished. Thus, the dynamic arrangement of interacting groups in the binding site, moulded in place by the imprinting process, can result in very specific interactions between the imprinted material and the targeted ligand. In this section, the selectivity of molecular imprinted polymers and other matrices will be discussed, focusing on their use in affinity separation.

Molecularly Imprinted Materials

Of all areas where molecularly imprinted materials have found applications, such as diagnostic assays,

drug delivery, sensor technology, and catalytic protocols, by far the most explored field is their use in separation science. Such materials have been developed for use in liquid chromatography (molecular imprinting chromatography, MIC), solid-phase extraction (SPE), capillary electrophoresis, membrane technology and library screening protocols. Especially, chiral discrimination has been heavily investigated, and a large number of impressive chiral separations have been performed. More detailed overviews with respect to chiral separation, as well as to SPE, by these materials can be found elsewhere in this Encyclopedia.

Affinity Separation

As is the case with all types of affinity-based separation techniques, imprint-based protocols can be considered as a mixed-type separation process. The recognition between the analytes and the matrix relies on both affinity-type interactions, exerted by the ensemble of interactions between the analyte and the matrix in the recognition site, and less selective processes, such as general ion exchange, metal coordination and hydrophobic interactions. Although this mixed-type separation can sometimes be advantageous in as much as it offers a means for the analytical chemist to control the retention, most often it is a drawback, and attempts have been made to mask unwanted recognition contributions. For example, the nonselective ion exchange contribution of charged moieties in the matrix can be chemically blocked, resulting in a material where only the charged groups in the sites are active (Figure 1).

The phenomenon of nonspecific binding can sometimes be difficult to distinguish from the affinity process, since a comparison between a material that has been imprinted to a nonimprinted blank can result in differences for compounds that should not be recognized. Since the physical properties of the material

Figure 1 Reduction of nonspecific binding by chemical blocking.

will inevitably change upon imprinting, a change in retention will also be found for compounds not selectively recognized by the material. For example, if a material is prepared using methacrylic acid as functional monomer, the resulting imprinted material may show more pronounced retention than its nonimprinted counterpart. This phenomenon can in part be attributed to the formation of carboxylate dimers in the blank material, thus displaying fewer carboxylate groups free to interact with the analytes. On the other hand, in the imprinted material the carboxylate groups take part in the recognition process and are more exposed to the analytes. Thus, in order to estimate the selectivity of imprinted materials, an estimate of the behaviour of both imprinted and nonimprinted matrices needs to be made. For a full investigation, the behaviour of two or more imprinted matrices is also a very useful comparison. The nonimprinted matrix will address nonselective contributions for a chosen eluent. A set of imprinted matrices will provide information on both the selectivity accomplished and the physical change introduced by the imprinting process. Of course, when chiral separations are targeted, the chiral discrimination in itself is proof of the accomplished selectivity, since a nonimprinted matrix will normally never show enantioselectivity (unless chiral building blocks are used).

Selectivity

As mentioned above, the selectivities that can be accomplished with molecularly imprinted materials are often on a par with natural binders such as antibodies and biological receptors. In most cases, however, this can only be achieved by careful consideration of the system chosen, with respect to the ligand and the building block functionalities. Although much of the beauty and attraction of the entire concept lies in its seemingly compliant facility, design is none the less imperative for the outcome of an efficient imprinting process. It is only after judicious control of all system parameters that highly selective materials can be produced. Rational design is thus involved in using interactions as specific as possible from the very start. Most of the bond types used are chosen in order to acquire a desired selectivity directly from the resulting interaction with its corresponding counterpart, and this selectivity can subsequently be further accentuated by the imprinting process.

Molecular Imprinting Protocols

The characteristics of the imprinting process depend very much on the strength of the bonds used between the ligand and the functional building blocks, ranging

Figure 2 The higher the bond energy used for point interactions, the higher the compliance of the positioning of the groups in the site, but the lower the applicability of the concept. For this reason, most protocols are based on noncovalent systems.

from strong, albeit reversible, covalent bonds to weak, noncovalent interactions. What can be gained from an increased strength between the ligand and the functional building blocks during the imprinting process is often a drawback during the utilization of the resulting materials, and vice versa if noncovalent bond types are used. If too strong bonds are used, such as carboxylic amides and esters, the ease with which the extraction/rebinding process can procure is strongly limited, requiring exceedingly harsh conditions. Thus, weaker bond types have to be employed (Figure 2). Amongst reversible covalent bond types that have been used are boronic esters, imines and disulfides, all easily reversible under reasonably mild conditions. However, only boronic acid esters have been successfully used in chromatographic systems, due to their faster exchange kinetics, which is a reflection of their very low bond strength in aqueous environments ($\Delta G \sim 12 \text{ kJ mol}^{-1}$ for the interaction between phenylboronic acid and glucose).

The special characteristics of metal coordination make these very useful for molecular imprinting. The binding strengths lie between covalent and noncovalent, and can be easily varied by exchange of the metal ion used. The bond energy for a commonly used building block, iminodiacetate (IDA) complexed with Cu^{2+} and imidazole, amounts to $\sim 20 \text{ kJ mol}^{-1}$ at room temperature in aqueous solution.

Although the use of reversible covalent bonds, as well as metal coordination, meets the prerequisite of strong interactions prior to fixation, these systems suffer from one serious drawback – only a limited number of ligands can be targeted using these bond types. Noncovalent interactions on the other hand permit a broader utility range that can be covered, largely making them more advantageous. This is in accordance with biological systems, where molecular complexes are often formed by a plethora of noncovalent interactions such as hydrogen bonds and ion pairing. Although these interactions, when considered individually, are weak compared to covalent bonds, the concerted action of several of these bond types often leads to complexes with very high stability. The high degree of specificity that can be achieved, in combination with the dynamic properties of the interactions, makes these bond types a prerequisite for many biological processes, and has also

been the preferred choice in many imprinting protocols.

Attempts to overcome the drawbacks from the respective protocols, but still be able to benefit from their advantages, can be made by combining the two extremes. Thus, protocols based on covalent binding during the fixation process, but switching to noncovalent interactions afterwards, have been designed, for example, successful protocols based on cleavage of esters, carbonates and amides.

Origin of Selectivity

The complex, normally macromolecular nature of molecularly imprinted materials has precluded a full understanding of the recognition mechanism between the analyte and the matrix. Physical methods, such as solid-state nuclear magnetic resonance, Fourier transform infrared, atomic force microscopy (AFM) and electron spin resonance (ESR), have revealed some of the characteristics of the materials, but a more detailed account of the site architecture remains to be resolved. In contrast, the complexes between the functional building blocks and the print species, formed in solution prior to any imprinting process, can be studied more easily. Obviously, the use of covalent interactions, and often metal coordination interactions, results in structures that can be well characterized by common physical organic methods. In noncovalent systems the situation is more complex, but the use of solution-phase methods has allowed a picture of the interactions to be drawn. Although imprinting of these complexes/adducts may change their structures considerably, the information that can be retrieved from such studies is nevertheless valuable.

The recognition of events taking place in encounters between ligands and receptors is highly dependent on the additive effect of a number of binding forces. An optimal combination of the potential binding forces may lead to strong binding. Thus, in order to achieve proficient complexation between the host molecule and the guest species, several factors such as shape complementarity, functional complementarity and contributions from the surrounding pool of solvent have to be considered.

In all imprinting protocols, be they based upon covalent or noncovalent interactions, the most important factor governing the substrate selectivity is the quality and number of point interactions used to form bonds in solution prior to fixation, gelation or polymerization. In self-assembly systems using noncovalent interactions, the main factors responsible for selective rebinding of ligands to the imprinted sites have been shown to be strong noncovalent bonds such as charge-charge interactions and hydrogen bonding.

Other types of interactions, such as π - π stacking and dipole interactions, may take part as well, but normally to a lesser extent. The three-dimensional arrangement of these interaction points, a reflection of the solution-phase situation set in place by the polymerization step, leads to an inherent specificity of the formed sites. Likewise, in metal coordination systems, the major points of interaction occur between the immobilized metal ions and the coordination sites of the analyte, and the reversible covalent interactions between the functional moieties of the matrix and their counterparts of the analyte make up the major interaction in covalent systems.

In addition to these point interactions, the architecture of the surrounding matrix determines the steric limits of the site, thus providing a more or less efficient van der Waals surface to the analyte. Although the arrangement of the functional moieties in the matrix accounts for most of the selectivity, the shape of the site also plays an important role. The configuration of the surrounding matrix backbone, as cast in place around the print molecule, contributes to the overall ligand specificity (Figure 3). This effect is sometimes less pronounced and substantial freedom in ligand structure can be observed, but often the effect is considerable and minute differences in size can be distinguished. In several cases, the position of a single methyl group is crucial for recognition. In this perspective, the shape effect of the site is particularly pronounced for parts of an imprinted molecule in close proximity to the point interactions. For structural features of the analyte more distal from such bonds, the shape is less important.

Forms of Selectivity

The topic of chemical selectivity can be categorized into three main groups:

1. chemoselectivity, i.e. differentiation among various functional groups in a polyfunctional molecule

Figure 3 Schematic representation of interactions between a chosen ligand (here captopril) and a molecularly imprinted material. In addition to possible point interactions, whether covalent (disulfide, acetal, ester) or noncovalent (hydrogen bonds, coulombic electrostatic), the backbone of the imprinted network may also contribute to overall selectivity.

2. regioselectivity, referring to orientational control of the interaction
3. stereoselectivity, specifying the control of stereochemistry in the recognition site

Sometimes the last group is further subdivided with reference to the control of relative stereochemistry (diastereoselectivity) and absolute stereochemistry (enantioselectivity). A further physical type of selectivity is the discrimination of molecular size – an issue that may be of substantial importance when dealing with macromolecules and solid matrices.

Chemoselectivity In imprinting protocols based upon reversible covalent bonds, such as boronate esters, disulfides and imines, the chemoselectivity is principally a consequence of the properties of the covalent bond type chosen. Thus, for boronate esters, *vic*-diols are preferred as they give more stable esters than, e.g., mono-alcohols or *gem*-diols, and disulfides are formed exclusively from thiols. Other bond types of a slightly more general character, e.g. acetals, selective for carbonyl groups/alcohols, and imines, selective for carbonyl/amino moieties, are however potentially useful in recognizing a wider variety of ligands.

In metal coordination systems, the coordination properties of the ligand-metal ion pair govern most of the chemoselectivity that can be expected. This programmed selectivity can easily be changed, simply by changing the metal ion. If such a molecularly imprinted material is charged with different metal ions, the coordination properties can be fine-tuned. Such a bait-and-switch strategy has been used for changing the binding strength from high affinity during the imprinting process to low affinity in the rebinding/separation process. For example, Cu(II) can be changed for Zn(II), since the latter displays a weaker

affinity for imidazole groups. When the ion itself is the target species (ligand), coordinating building blocks are normally chosen to occupy less than or equal to half of the coordinating bonds of the ion, allowing for adaptation during the imprinting process (Figure 4). The ionic recognition that can be achieved with such systems is often remarkable, and systems that are able selectively to distinguish small differences in ionic size and coordination pattern have been designed.

In noncovalent systems, the chemoselectivity is much less obvious in the design of the interactions. If a print molecule contains charges or hydrogen-bonding moieties, and functional monomers are chosen accordingly, the inherent chemoselectivity in the complexes formed is less strong, and other ligands can compete for the interactions as well. In addition, the functional building blocks, as well as the ligands, may self-interact to some extent. Nevertheless, a dramatic chemoselectivity can be accomplished when the strength of the noncovalent interaction is altered, for example, by introducing substituents which change the electronic density of a compound, or substituting a hydrogen taking part in a hydrogen bond. For example, caffeine (**1b**) binds very poorly to a molecularly imprinted material prepared against theophylline (**1a**), only differing in the exchange of a hydrogen for a methyl group, and the exchange of a hydroxyl group for a keto group in cortisol/cortisone (**2a/2b**) results in a remarkable loss in binding (Figure 5).

More elaborate systems, which can recognize certain motives in a given ligand, can however be designed. For example (Figure 6), the barbiturate structure (**3**), displaying two acceptor–donor–acceptor hydrogen bonding motifs, can be very selectively recognized in solution by a corresponding amidopyridine (**4**) displaying a donor–acceptor–donor counterpart. In comparison with monovalent functional mono-

Figure 4 Metal ions can be very selectively recognized by imprinted matrices. For example, Hg(II) can be distinguished from Cd(II), Pb(II) and Cu(II) by the imprinted structure (A). Similarly, material (B) could selectively separate Ca(II) and Mg(II).

Figure 5 Examples of high chemoselectivity in noncovalent systems. Caffeine (**1b**) and theophylline (**1a**) differ only in one methyl group. Nevertheless, caffeine does not bind to matrices prepared against theophylline. Similarly, cortisone (**2b**) binds poorly to an anticortisol (**2a**) polymer.

mers, a high chemoselectivity can be designed for a chosen structure prior to the imprinting process. On the other hand, if a carefully designed multipoint system does not allow for dynamic adjustment, not much is gained from the imprinting process. In this example, the general structure (**3**) is well recognized, irrespective of R and R' .

In all these cases, however, the chemoselectivity that is more or less rationally designed upon examination of the target print species can be radically enhanced by the imprinting process. This is particularly the case when dealing with less specific noncovalent interactions. The positioning of the functional groups in the three-dimensional network of the matrix, together with the formation of the site or imprint, often results in a tremendous increase in specificity.

Regioselectivity Regioselectivity can often be nicely demonstrated by molecularly imprinted materials using all types of imprinting protocols. In this case, the imprinting process *per se*, rather than the bond type, endows high regioselectivity. It is mainly due to proper three-dimensional (or two-dimensional) positioning of the functional building blocks in the finally produced matrix that high selectivity can be accomplished. Sometimes, however, the selectivity is also

a consequence of the architecture of the surrounding backbone of the imprinted matrix in addition to organized point interactions. Obviously, this works concertedly, such that the build-up of the matrix backbone may force the originally noninteracting parts of the functional building blocks to accommodate a position, resulting in steric hindrance of different analytes.

A number of systems have been designed where *bis*-functional compounds displaying a difference in distance between the point interactions can be efficiently distinguished by the produced matrix. For example, a range of either *bis*-aldehydes (**5a/5b**) or diketones (**6a/6b**) could be selectively discriminated by matrices produced using imine- and acetal-formations, respectively (**Figure 7**).

Another example is the imprinting of *bis*-imidazole structures using Cu(II) coordination. A selectivity between the structures could be recorded, largely dependent upon the positioning of the Cu ions in the material. In these examples, the distance between the point interactions can be considered as being of major importance for recognition.

Similar studies have been pursued using noncovalent interactions, e.g. the interactions of *bis*-pyridyl and *bis*-aniline compounds with carboxylic acids, which show high distance selectivities also.

Although investigations of such *bis*-compounds can be considered as interesting model studies, proving the utility of the imprinting concept, many examples of compounds of more practical interest, e.g. food additives or drugs, have been examined. Steroids, for instance, are a class of compounds that lends itself to being both interesting model systems as well as commercially important, and several impressive steroid separations have been demonstrated. For example, β -11-OH-progesterone (**7a**) can be most selectively separated from β -17-OH-progesterone (**7b**) (**Figure 8**), in part due to the reasonably rigid steroid framework, which helps to lower the entropy loss upon steroid binding compared to a more flexible molecule.

Figure 6 Multiple hydrogen bonding between cyclobarbital (**3**) and *bis*-amidopyridines (**4**).

Figure 7 Distance selectivity in reversible covalent systems. Bis-aldehydes **5a/5b**, and bis-ketones **6a/6b** could be distinguished by matrices prepared against one of the structures using imine and ketal formation, respectively.

Stereoselectivity The physical properties of enantiomers, i.e. identical properties in a symmetrical environment, render them ideal substrates for the study of imprinting specificity. This is one of the reasons why this aspect has been the most extensively studied in MIT in general, and in MIC in particular. Indeed, this quality offers the clearest evidence for the outcome of a successful imprinting process. Obviously, if chiral discrimination can be introduced in a matrix through an imprinting process, based upon exclusively achiral building blocks, an indisputable demonstration of the concept is obtained.

A large number of investigations concerning chiral separations by molecularly imprinted materials have been performed, and hardly any type of compound has been neglected from examination. Thus, compounds such as amino acids, carbohydrates, nucleic acids and pharmaceuticals have all been applied in various imprinting protocols. The stereoselectivity that can be achieved is also quite extraordinary, and differences in binding of single hydroxyl groups (*R*- and *S*-timolol), and even single methyl groups can sometimes be observed (*R*- and *S*-naproxen). The interested reader can find a more detailed overview of chiral separations using molecularly imprinted materials elsewhere in this Encyclopedia (Kempe M,

Chiral Separation: Molecular Imprints as Stationary Phases).

Conclusions and Future Prospects

MIT is a technique that has substantially improved over the last few years. Many of the drawbacks initially encountered have gradually been overcome, and intense research is ongoing to resolve some of the remaining challenges. As has been pointed out, the technique is already competent at recognizing very small structural differences, and the ultimate venture that prevails in this respect is the separation of isotopes. Another task that needs further attention, although some steps have already been taken in this direction, is the selective recognition/separation of biological macromolecules, and even whole cells.

For affinity separation, however, high affinities may not always be the ultimate goal. High affinities sometimes lead to situations where elution from the affinity matrix requires harsh condition. For this reason, a material providing a lower affinity can sometimes be advantageous, and the process of binding/elution can be accomplished using mild conditions. Likewise, a high selectivity is not always a goal in itself, and materials with lower selectivity

Figure 8 Examples of the high regioselectivity that can be achieved by matrices produced against steroids. β-11-OH-progesterone (**7a**) and β-17-OH-progesterone (**7b**) were efficiently separated by a molecularly imprinted chromatographic stationary phase. The androstene-triol (**8**) could be selectively acetylated in the 11-position upon protection/binding to the matrix.

can also be preferable. This is the case when performing separations of groups of molecules rather than a single species, such as the recognition of the β-lactam group as a whole, rather than individual penicillins. Using materials that are apt at recognizing a ‘molecular chord’, rather than single ‘molecular notes’, can sometimes be beneficial.

The Nature of the Technique

The technique of silver ion chromatography, which is sometimes termed 'argentation chromatography', was first introduced for the separation of fatty acid derivatives in two papers which appeared almost simultaneously in *Chemistry* and *Industry* in 1962. In its earliest manifestations, it was adapted to thin-layer chromatography (TLC) and to low pressure column chromatography. The former is still in widespread use today, but high performance liquid chromatography (HPLC) has more recently been adapted to the purpose and may be expected to slowly supplant TLC. Gas chromatography with stationary phases containing silver ions has been used to separate mixtures of hydrocarbons containing low molecular weight olefins, but is not practical for analytes of higher molecular weight. While lipid chemists, especially those concerned with fatty acid derivatives, have made most use of silver ion chromatography, it has also been used for a wide range of aliphatic and alicyclic compounds, including terpenes, sterols, carotenoids, insect pheromones, etc. However, applications only to separation of more conventional lipids will be described here as examples of what can be accomplished. A number of review articles have appeared, that by Morris (1966) covering the early literature and those by Nikolova-Damyanova and colleagues (Nikolova-Damyanova, 1992; Dobson *et al.*, 1995) bringing the topic up to date. Details of practical methods are given in a book by Christie (1989).

Silver ion chromatography is based on a distinctive property of unsaturated organic compounds, that is the capacity to complex with transition metals in general, and with silver ions in particular. The complexes are of the charge-transfer type in which the unsaturated compound acts as an electron donor and the silver ion as an electron acceptor. In the accepted model, it is believed that there is formation of a σ -type bond between the occupied 2p orbitals of an olefinic double bond and the free 5s and 5p orbitals of

the silver ion, and a (probably weaker) π -acceptor backbond between the occupied 4d orbitals of the silver ion and the free antibonding 2p π^* orbitals of the olefinic bond. In chromatographic systems, complexes are only formed transiently and are in kinetic equilibrium with the free olefin. The coordination forces are weak, and IR spectra show very little shift in frequencies from those of free double bonds, for example. Stable silver ion-olefin complexes have been isolated in some circumstances, and then X-ray crystallography has demonstrated that each silver ion can interact with two double bonds simultaneously. Other metals can form such complexes but none other than silver has the correct combination of properties for general chromatographic use.

Until recently, the technique was very much an *ad hoc* one that worked, but without a sound theoretical basis. Silver ion TLC cannot be used to generate reproducible chromatographic data, for example. However, some useful qualitative data are available from studies with simple model compounds and in particular it is apparent that:

- Unsaturated aliphatic and alicyclic compounds form more stable complexes than do aromatics.
- The stability decreases with increasing chain length of the aliphatic substrate.
- The stability decreases with increasing numbers of substituents of a double bond in the order $RCH=CH_2 > R_2C=CH_2 > cis\ RCH=CHR > trans\ RCH=CHR > R_2C=CHR > R_2C=CR_2$. The greater stability of the *cis*-isomer may be due either to the relief of strain when the complex is formed or to steric hindrance by the two alkyl moieties when they are in a transposition to each other.
- Conjugated polyenes form less stable complexes than do those with methylene-interrupted double bonds, and the greatest stability is when two methylene groups separate double bonds, perhaps because a chelate complex can then be formed.
- The stability of a silver ion complex increases when a hydrogen atom from a molecule of the $RCH=CHR$ type, for example, is replaced with deuterium or tritium.
- Monoenes form stronger complexes than monoynes (one acetylenic bond).
- The strength of complexation increases as the temperature is lowered.

As far as has been ascertained, these rules also apply to larger molecules such as simply fatty acid

derivatives, and to all forms of silver ion chromatography. However, there are few quantitative experimental or theoretical data on the mechanism of complex formation between silver ions and complicated unsaturated molecules like glycerolipids, which have up to three unsaturated fatty acids per molecule, although again, there is a substantial body of qualitative information.

A complicating factor, when considering silver ion complexation in the context of a chromatographic system, is the role of the support material. The most widely used support for TLC, silica gel, possesses appreciable polarity and absorptive activity. Therefore, the elution order of lipids cannot always be ascribed to the complexation reaction with silver ions and double bonds only, although this is usually the most important factor. A separate but related problem is the topology of silver ions on the surface of the adsorbent. For example, in silver ion TLC it is apparent that part of the silver nitrate remained in crystalline form filling the pores of the silica gel while a further proportion remains dissolved in the water which is always bound to silica gel. The aqueous silver nitrate is assumed to be responsible for complex formation, and some experience seems to confirm this observation. For example, Nikolova-Damyanova considers that there is no need for incorporation of excessive amounts of silver nitrate ($> 1\text{--}2\%$) into TLC systems.

When discussing mixed retention mechanisms in chromatography, it is also necessary to consider the mobile phase. A proper choice of solvents determines the selectivity of a separation to an appreciable extent. Again, there are no systematic data available, but it has often been noted that better resolution is achieved by using chlorinated solvents as major components of the mobile phase in silver ion chromatography.

The more recent marriage of silver ion chromatography with HPLC has given us a better understanding of the mechanism of silver ion chromatography and this is discussed below.

Silver Ion Thin-Layer Chromatography

Silver ion TLC uses simple equipment and can afford excellent results in practice. Precoated TLC plates are available commercially, although it is not difficult to prepare one's own (but wear gloves!). Thus, silver nitrate is simply incorporated into the aqueous slurry used to suspend the silica gel and the plates are spread and activated in the usual way, though some care is necessary to minimize exposure to light. Sometimes 10–20% of silver nitrate relative to silica gel is recommended by authors, but 1–2% is generally sufficient.

Alternatively, plates can be impregnated with silver nitrate by careful immersion in a bath of a solution of silver nitrate in methanol or acetonitrile, and this option is often favoured with precoated TLC plates. After the plates have been activated, they should be stored in a desiccator in the dark.

Lipids are spotted on to the TLC plate and this is usually developed in a closed tank (in the dark) containing an appropriate mobile phase. However, Nikolova-Damyanova recommends using open tanks and carefully regulated volumes of solvent. Chromatography is most often carried out at ambient temperature, although temperatures as low as -20°C have on occasion been recommended to increase the strength of complexation and improve the separation. When the mobile phase nears the top of the plate, the latter is removed from the tank, and dried in a stream of air or nitrogen.

Various methods of detection and quantification are available. For example, one popular method consists in spraying the plate with concentrated sulfuric acid, and heating it at 180°C in an oven. The separated components are charred (converted to carbon) and can be quantified directly by scanning densitometry. A procedure of this kind is of course destructive to the sample, and has to be carried out with great care to avoid hazard to the operator.

Alternatively, the developed plate can be sprayed with a solution of 2',7'-dichlorofluorescein in methanol (0.1% w/v). After evaporation of the solvent, the plate is viewed under a UV lamp; lipids appear as yellow spots against a dark purple background. The lipid/silica gel spots are scraped from the plate, and lipids are recovered by extraction with an appropriate solvent, though the extracts may have to be washed with a solution of dilute buffer (pH 9) to eliminate any silver nitrate and dye that co-elute. Commonly components are identified and quantified by gas chromatography of the fatty acid methyl esters, following transesterification, in the presence of an added internal standard, such as an odd-chain fatty acid.

As an example, **Figure 1** illustrates the separation of fatty acid methyl esters by silver ion TLC. Saturated fatty acids do not form complexes with silver ions, so migrate ahead of the other components on the plate. *Trans*-monoenes form less stable complexes than *cis*-monoenes, so the former migrate faster. Dienoic fatty acids come next followed by polyenes, which under these conditions remain near the origin. A separation of this kind is the standard method for reliable quantification of fatty acids with *trans* double bonds. If the polarity of the mobile phase is increased, polyenoic fatty acid derivatives can be resolved into fractions with three, four, five and six double bonds, but saturated, and mono- and

Figure 1 Silver ion TLC (Kieselgel GTM containing 2% silver nitrate) of fatty acid methyl esters, with hexane/diethyl ether (9 : 1, v/v) as mobile phase.

dienoic fatty acids will then run together near the solvent front.

Figure 2 is a schematic representation of a silver ion TLC separation of triacylglycerols (which can include all the common oils and fats of commerce), which contain three fatty acids per molecule. In this instance, trisaturated species elute first followed by disaturated monoenoic; the latter separating into two fractions (more or less completely) according to whether the unsaturated fatty acid is on position 2 of the glycerol moiety or in one of the outer positions. Then, the monosaturated dimonoenoic species is eluted followed by a fraction containing one dienoic fatty acid with two saturated, i.e. a dienoic fatty acid is retained more strongly than two monoenes, and so on.

Phospholipid molecular species have been resolved in this way also, both in intact form (technically difficult) or after enzymatic conversion to non-polar diacylglycerol derivatives.

Although the equipment is simple and inexpensive, there are many drawbacks to silver ion TLC procedures, not least that silver ions are eluted from TLC plates and contaminate fractions in preparative applications, as do silica gel and dyes used for detection purposes. Silver nitrate leaves indelible stains on

benches, equipment and the fingers of the analysts. HPLC methods do not suffer from these difficulties.

Preparative Scale Column Chromatography

By analogy with silver ion TLC it has proved possible to impregnate silica adsorbents (or better, acid-washed FlorisilTM) with silver nitrate and pack into columns to enable separation of fatty acids by degree of unsaturation. However, the technique suffers from many of the problems associated with silver ion TLC.

As an alternative, macroreticular sulfonic acid ion exchange resins have been utilized as adsorbents for silver ion column chromatography. The resin is loaded with silver ions by passing an aqueous solution of silver nitrate through a column of resin until excess silver ions start to elute. The column is then washed with water and methanol, and methanol is used further as the mobile phase. Recently, Amberlyst XE 284TM has been shown to give the best results, but the separations improved significantly only when the mobile phase of methanol was modified with

Figure 2 Silver ion TLC (Kieselgel GTM containing 10% silver nitrate) of triacylglycerols, with chloroform/methanol (99 : 1 v/v) as mobile phase. Abbreviations: S = saturated, M = *cis*-monoenoic and D = dienoic fatty acyl residues.

acetonitrile, which enabled a good resolution of monoenes, dienes, trienes and tetraenes (DeJarlais *et al.*, 1983). Further improvements were obtained by grinding the resins first to 270–350 mesh.

This technique permits fractionation of mixtures of unsaturated fatty acids by degree of unsaturation on the 10 to 20 gram scale. As the silver ions are held by ionic bonds, they are not leached from the column and clean fractions are obtained. However, the range of mobile phases that can be employed is limited, otherwise swelling and compaction of the resin will occur.

Silver Ion High Performance Liquid Chromatography

The approach to silver ion HPLC adopted by Christie (1987) is to load a silica-based ion exchange medium (chemically bonded phenyl sulfonic acid groups) with silver ions. Again, the silver ions are held by ionic bonds and are not leached from the column, while rigidity of the silica matrix prevents compaction of the packing material during gradient elution. Preparation of the column involves merely taking a standard prepacked column with the appropriate stationary phase (Nucleosil™ 5SA) and introducing the silver ions via an injector while pumping water through the column. Finally, the aqueous phase is replaced with organic solvents. Only 50 to 80 mg of silver ions are bound to the stationary phase, but this is quite sufficient for very many useful separations.

Lipids lack chromophores that facilitate UV detection, although it is possible to use UV detection with appropriate fatty acid derivatives. Therefore, for much of the work with silver ion HPLC columns, evaporative light-scattering detectors have been employed as they permit the use of complex gradients and mobile phases containing such solvents as dichloromethane and acetone. Although the detector is destructive in that the sample is lost in the current of air, it is possible to insert a stream splitter between the end of the HPLC column and the detector to divert much of the sample for collection.

Chlorinated solvents, such as dichloromethane or dichloroethane, form the basis of the more useful mobile phases, and the polarity can be increased to elute highly unsaturated components by adding acetone or especially acetonitrile, which has a high affinity for silver ions. Presumably the high dielectric constant of the chlorinated solvents facilitates the interaction between silver ions and the double bonds. However, acceptable results can also be obtained with hexane as the main component of the mobile phase if a little acetonitrile is present.

Methyl esters are the most widely used fatty acid derivative for chromatography, because of the ease of preparation and their relatively low molecular weight. One useful application of silver ion HPLC is the separation of such derivatives from animal or fish lipids, into fractions with zero to six double bonds. Simplification of complex mixtures by this means makes the task of identification by other chromatographic means or by mass spectrometry much easier.

However, by an appropriate choice of solvents, it is possible to separate positional and geometrical isomers of unsaturated fatty acids on a micro-preparative scale, a feat not readily achieved by other chromatographic procedures. For example, the separation obtained with phenacyl esters of the three main naturally occurring octadecenoic acid isomers is illustrated in **Figure 3**; all are clearly resolved to baseline. It has become evident that the distance of the double bond from the carboxyl group is more important in governing the separation of positional isomers than is the terminal region of the molecule. Phenacyl derivatives of fatty acids were prepared at first so that quantification with UV detection was possible, but fortuitously, it has now become apparent that such derivatives give especially favourable separations (and this is also true for silver ion TLC). This technique can be used with equal facility for the separation of simple fatty acid derivatives with *trans* double bonds, and will undoubtedly supplant TLC for the purpose. Positional isomers of polyunsaturated fatty acid derivatives can be resolved similarly by increasing the polarity of the mobile phase.

Silver ion HPLC is also of great value for separation of molecular species of triacylglycerols. The simplest elution scheme is a gradient of acetone into dichloroethane–dichloromethane, which serves for fats with low levels of linoleic acid, such as sheep adipose tissue or bovine milk fat. This

Figure 3 Separation of phenacyl esters of the isomeric octadecenoic acids, petroselinic (6-18:1), oleic (9-18:1) and vaccenic (11-18:1), by HPLC on a Nucleosil™ 5SA column in the silver ion form eluted with dichloromethane/dichloroethane/acetonitrile (50:50:0.25 by volume), with evaporative light-scattering detection.

gives resolution of the main components with zero to three double bonds in total in the fatty acyl chains, including separation of fractions with *trans*- from those with *cis*-monoenoic residues. Most triacylglycerol samples are likely to contain appreciable proportions of linoleic acid, and resolution into molecular species is then accomplished by ternary gradient elution, simply by introducing acetonitrile into acetone after the first fractions are recovered. Such a separation of adipose tissue triacylglycerols is illustrated in Figure 4. One dienoic acyl moiety is retained more than twice as strongly as a monoene, and one triene (18 : 3 (*n*-3)) is retained by the same amount as two dienoic residues in a molecule, so there is some overlap of dienoic and trienoic species when α -linolenic acid is present in a sample. Otherwise, the basis of the separation is similar to that described earlier for TLC applications, in that trisaturated species elute first, followed by disaturated monoenoic and so forth.

Such highly unsaturated triacylglycerols as linseed oil and fish oils have been resolved satisfactorily. With the former, trilinolenin is the most abundant single fraction, and a simple progression of fractions with increasing numbers of double bonds are eluted until this species is reached. When the more saturated molecules of fish oils are eluted, resolution is excellent and it is perhaps surprising to find appreciable amounts of trisaturated and disaturated monoene species. Baseline resolution is no longer possible when molecules containing polyunsaturated fatty acids begin to elute, because the wide range of positional isomers causes similar components to overlap. Nevertheless, valuable separations of species contain-

ing two saturated and/or monoenoic fatty acids and one polyenoic fatty acid especially can be achieved.

In silver ion chromatography, the order of elution of triacylglycerol species is easily understood because only one property of the molecules is involved, i.e. degree of unsaturation. The alternative technique used for molecular species separations is reversed-phase chromatography, with octadecylsilyl phases, which effects separation both by chain length and degree of unsaturation, each double bond reducing the effective chain length by the equivalent of about two methylene groups. When used in sequence the two techniques make a much more powerful tool. Fish oils give highly complex chromatograms with reversed-phase HPLC, for example, and identification of individual components is impossible. On the other hand, when fractions from silver ion HPLC are collected and then subjected to reversed-phase HPLC, separation is then, in effect, by chain length only and the main peaks are easily identified. Each HPLC fraction can be examined in turn in this way, and much more information obtained in comparison to the use of either technique on its own.

Some Mechanistic Considerations

In silver ion HPLC, we have a reasonable understanding of how the silver ions are bound to the stationary phase via the phenylsulfonic acid groups. There may be some residual silanol groups on the surface of the silica matrix, but these should not influence separations greatly when relatively polar chlorinated solvents are used in the mobile phase. Also in HPLC, we can control both the composition and flow rate of the mobile phase with a high degree of accuracy. Finally, we can control the temperature of the column, an important factor in the complexation reaction between silver ions and double bonds. Accurate chromatographic retention data can thereby be obtained for a variety of lipid analytes of known structure.

It is known that silver ions can interact with two double bonds in a fatty acyl residue at the same time, but can they also react with one double bond and the unpaired electrons on the carboxyl moiety as shown schematically in Figure 5? This might explain how different positional isomers of fatty acids are separable by this technique. For example, electron-rich esters, such as the phenacyl derivatives illustrated, are held much more strongly than are methyl esters when the double bond is within about eight carbons of the carboxyl group, and the elution patterns of series of isomers are very different. From a 9-18 : 1 fatty acid derivative onwards, when the possibility of such a simultaneous interaction would seem to be less likely, there is no significant difference between methyl and phenacyl

Figure 4 Separation of triacylglycerols from rat adipose tissue by HPLC on a Nucleosil™ 5SA column in the silver ion form, with evaporative light-scattering detection. Abbreviations: S, saturated; M, monoenoic; D, dienoic; T, trienoic fatty acyl residues. (Adapted from Christie, 1988.)

Figure 5 Schematic representation of the interaction of a silver ion with the phenacyl ester derivative of petroselinic acid.

esters. Experiments with esters with a variety of different electron-donating and electron-withdrawing substituents now provide firm evidence for this hypothesis.

An interaction between one silver ion and two double bonds at the same time may explain the chromatographic behaviour of fatty derivatives with two or more double bonds in the acyl chain in silver ion HPLC. When the distance between the double bonds is optimum, i.e. with a 1,5-*cis,cis*-diene system, fatty acids are very strongly retained, and the effect diminishes as the number of methylene groups between the double bonds is varied. If the double bonds interacted singly with silver ions, it might have been anticipated that the kinetics of the system would be such that retention would be comparable in magnitude to the sum of the individual parts, but this is clearly not so. This theory of complexation between silver ions and bis-double bond systems could potentially be applied to polyenoic fatty acid derivatives. It would predict that a triene would be held twice as strongly as a diene, a tetraene three times as strongly and so forth. Such a simple relationship is not found in practice (the degree of complex formation is even greater than anticipated), possibly because interactions with the ester moiety have to be taken into consideration and because the conformations of polyenes may permit some interactions between silver ions and double bonds that are remote from each other, via the formation of pseudo-cyclic structures.

Analogous physicochemical studies of the behaviour of triacylglycerols on silver ion chromatography suggests that a dual interaction is important in this instance also. For example, it has been shown that highly unsaturated triacylglycerols are retained especially

strongly; a species with nine double bonds is held 10 000 times as strongly as one with a single double bond. It is the strength of this interaction rather than the efficiency of the column *per se* that is responsible for the quality of the separations. However, here further work is certainly necessary to confirm the mechanism.

Introduction

Silver ions (Ag^+), like the ions of many other transition metals, interact specifically with

Table 1 List of compounds subjected to Ag-TLC

Class	Compounds
Lipids	Fatty acid mixtures
	Isomeric octadecenoic and octadecadienoic fatty acids
	Furanoid fatty acids
	Cyclopropene fatty acids
	Oxygenated unsaturated acids
	Triacylglycerol mixtures of natural fats and oils of terrestrial and marine origin
	Phospholipids
Terpenes	Sterol esters
	C ₁₀ , C ₁₅ , C ₂₀ terpenes
	Terpene alcohols
Hydrocarbons	Monoterpenes
	Acyclic olefines
	Alkylbenzenes
	Alkylphenylsulfides
Miscellaneous	Steroids
	Sterols
	Sterol acetates
	Derivatized unsaturated aldehydes and ketones
	Prostaglandins
	Hydroxyprogesterones
	Estrogens
	Mineral oils

unsaturated compounds to form complexes with olefinic double bonds. In 1938 Winsten and Lukas and in 1952 Nichols demonstrated that the interaction between Ag^+ and double bonds might be of interest for chemical analysis. By applying a liquid-liquid distribution system with Ag^+ present in the aqueous phase it was possible to separate easily unsaturated from saturated compounds and *E*- from *Z*-monounsaturated olefins. The great potential of this interaction for separation of unsaturated compounds was fully recognized when gas-liquid chromatography (GLC) and thin-layer chromatography (TLC) developed into routine analytical techniques.

The chromatographic technique that utilizes the interaction between Ag^+ and an olefinic bond to conduct the separation process is now called argentation (silver ion) chromatography. Argentation chromatography was first developed as a GLC technique. However, argentation TLC (Ag-TLC) soon became a basic separation method for the analysis of different types of unsaturated compounds. For many years it has been a most valuable method in lipid analysis, providing essential information about the lipid structure and composition.

Compounds that have been most frequently examined by Ag-TLC are listed in Table 1.

Silver Ion Complexation with Double Bonds

The model now considered to represent correctly the bonding between Ag^+ and a double bond was suggested by Dewar in 1951. It supposes the formation of a σ -type bond between the occupied $2p\pi$ orbitals of an olefinic double bond and the free $5s$ and $5p$ orbitals of the Ag^+ , and a (probably weaker) π -acceptor backbond between the occupied $4d$ orbitals of the silver ion and the free antibonding $2p\pi^*$ orbitals of the olefinic bond (Figure 1).

It is suggested that a silver ion interacts with one mono-olefin molecule to give a planar complex with a triangular structure. However, there is evidence that a silver ion may interact with two ethylenic molecules. X-ray studies of crystalline silver ion complexes with some short chain aliphatic diolefins show that the Ag^+ is coordinated with two double bonds from different olefinic molecules.

The stability of the silver ion-double bond complex is influenced by the spatial arrangement of the overlapping orbitals, the basicity of and electronic effects in the olefinic molecule, and by solvent effects. Quantitative data (for example equilibrium constants) exist only for a number of short chain mono-olefins, diolefins with accumulated, conjugated and separated methylene-interrupted double bonds, and for some cyclopenta- and cyclooctadienes. Most of these data, as well as the estimation of the relative strength of other complexes, are based on chromatographic measurements.

The general conclusions about complex formation reached so far are as follows:

1. Unsaturated acyclic and carbocyclic compounds form more stable complexes than do aromatics.
2. Carbocyclic compounds with a single exocyclic double bond form stronger complexes than do carbocyclic compounds with a single internal double bond. Cyclopenta- and cyclooctadienes

Figure 1 Schematic presentation of the interaction between a silver ion and a double bond.

form very stable complexes, especially when having a 1,5-diene system.

3. For acyclic compounds it has been found that:
 - the stability decreases with the increasing chain length;
 - the stability decreases with an increasing number of substituents at the double bond in the order $\text{RCH=CH}_2 > \text{R}_2\text{C=CH}_2 > \text{R}_2\text{C=CHR} > \text{R}_2\text{C=CR}_2$;
 - the stability increases when a hydrogen atom from a molecule of the RCH=CHR type is replaced with deuterium or tritium atom. The effect has been ascribed to greater electron release from a C–D than from a C–H bond, i.e. to the higher basicity of the deuterated molecule;
 - *cis* (*Z*)-isomers form stronger complex than do *trans* (*E*)-isomers. The greater stability of the *cis*-isomer is ascribed either to the relief of strain when the complex is formed or, more probably, to the steric hindrance of the double bond in *trans*-isomers;
 - diolefins form more stable complexes than do mono-olefins, but conjugated dienes form less stable complexes than do those with methylene-interrupted double bonds;
 - the stability increases with increasing distance between the double bonds. The most stable diene complexes are formed by the 1,5-diene system, perhaps because a chelate complex can be formed in the latter case.

Generally, the rate of complex formation for most acyclic compounds is very rapid. The complexes are usually unstable and exist in equilibrium with the free form of the olefin. The coordination forces seem to be very weak. The IR spectrum, for example, shows very little shift in frequencies from those of free double bonds. These particular properties of complexation between a double bond and a silver ion are favourable for use in chromatography.

The Technique of Ag-TLC

The Layer

Argentation TLC is utilized in two modifications: analytical and preparative. Both home-made and precoated plates (glass only) are used. Plate dimensions may vary from 5 cm × 20 cm to 20 cm × 20 cm. High performance TLC plates (HPTLC) have recently been found to be useful. Home-made layers, despite their messy preparation, are more versatile and often provide better separations than commercially prepared ones. Common adsorbents are listed in Table 2.

The thickness of the adsorbent layer ranges from 0.2 to 0.3 mm for analytical plates and from 0.5 to 1.0 mm for preparative plates. Fully automated spreaders for home-made layers are commercially available but simple spreaders are equally effective. However, some practice is needed for layer preparation and precoated plates are now mostly preferred.

The Incorporation of Silver Ions

There are two general ways to perform silver ion TLC of which by far the most common is to use a layer of adsorbent impregnated with a silver salt. It is possible as an alternative to add a silver salt to the mobile phase when a reversed-phase TLC separation is performed. This approach has found limited use only. Although the influence of the salt anion has not been studied systematically, there is evidence that its nature may affect the resolution. A list of silver salts used and their supposed effect is shown in Table 3.

Impregnation can be performed by incorporating the silver salt into the slurry of adsorbent used to make the layer. Also, the prepared plate can be immersed in a methanol, acetone or acetonitrile solution of the silver salt or sprayed with one of these solutions. Only the first approach affords proper control of the silver content of the layer. However, it is inconvenient and messy and is now rarely used. Since

Table 2 Adsorbents, frequently used with Ag-TLC

Adsorbent	Compounds to be separated	Comments
Silica gel G (binder is calcium sulfate)	Fatty acids	Fatty acids should be first converted into methyl esters.
	Triacylglycerols	Components are separated as intact compounds.
	Diacylglycerols	Compounds are separated after conversion into acetates.
	Polar lipids	Polar lipids should be converted into less polar derivatives, either by removing or by derivatizing the polar head.
	Terpenes	Compounds are usually separated as intact compounds.
Silica gel H (no binder)	Polar lipids	It is possible to separate polar lipids as intact compounds on this layer.
Alumina	Fatty acids	Species are separated as free fatty acids and as methyl esters. Alumina as adsorbent should be used with care since it is known to react with some analytes and solvents.

Table 3 List of silver salts used in Ag-TLC

<i>Salts</i>	<i>Components to be separated</i>	<i>Comments</i>
Silver nitrate	Fatty acids derivatives Triacylglycerols Polar lipids Terpenes	The most frequently used silver salt with very broad application for various separations. Silver salts other than silver nitrate are supposed to improve the separation.
Ammonia solution of silver nitrate	Fatty acid methyl esters	
Silver sulfamate	Fatty acid methyl esters	
Silver benzenesulfonate	Fatty acid methyl esters	
Silver iodate	Terpenes	
Silver perchlorate	Terpenes	

it appears that the content of silver ions in the layer may not, in fact, be critical, immersion procedures are mostly used. They can be standardized sufficiently well to provide repeatable results. Spraying procedures are less easily controlled. Spraying may have to be repeated from two to six times until the adsorbent layer is properly wetted. Sufficient spraying of the layer is somewhat arbitrary and depends on personal skill and on the samples to be examined. Immersion or spraying are only applicable to precoated plates. These plates should be immersed in a silver salt solution (methanol or acetonitrile) for not less than 15–20 min. A dynamic impregnation technique has also been proposed. The plate is developed with a 10–20% solution of silver nitrate in acetonitrile. It has been claimed that in this way a gradient of silver ions is formed in the development direction. The gradient is claimed to improve the separation of triacylglycerols. The approach has not found wide application and its advantages cannot be estimated.

The silver content of the adsorbent layer varies between rather broad limits and differs for analytical and preparative plates (Table 4). Layers containing a high percentage of silver nitrate were considered necessary to achieve good analytical resolution. This high percentage is, however, very inconvenient. The plates are very sensitive to light and this can greatly hamper detection and quantification. Impregnation by immersion in 0.5% methanolic silver nitrate provides excellent results in the

resolution of lipids, for example, without this disadvantage.

Treatment of the Plates and Precautions

Plates should be used immediately after being dried in air (for 1 h). Many workers activate the plates before use by heating at 110°C for about 1 h. However, good results have been reported after activation for only 5 min. Thus, it seems that the necessity for activation is questionable, and the analyst must trust to his or her own experience and the nature of the samples that are being handled. Activation has been found to be very important for silica gel H plates and temperatures higher than 110°C for periods of much longer than 1 h have been recommended.

Atmospheric humidity has an appreciable effect on separation, especially of highly unsaturated species. It is recommended that activated TLC plates be kept in a desiccator over drying agents (ideally in the dark). However, it is not easy to control humidity in practice. This may be one of the reasons for the relatively poor overall reproducibility of migration and resolution in separations performed by Ag-TLC.

Sample Preparation

Terpenes and triacylglycerols are applied as solutions of appropriate concentration in suitable solvents. Preliminary fractionation and purification from accompanying compounds is required. Fatty acids should be converted into less polar derivatives, usually into methyl esters. Recently, aromatic derivatives of fatty acids have proved to provide much better separation of difficult-to-resolve mixtures. Ag-TLC has not been very successful in separating intact complex lipids. Most of the reported procedures employ preliminary fractionation into specified classes and conversion of the latter into less polar derivatives.

Sample size is an important factor since overload greatly worsens the resolution. Analytical Ag-TLC on 0.2 mm thick layers requires samples of a maximum

Table 4 Concentration of the silver nitrate solutions and methods for impregnation of a TLC layer

<i>AgNO₃ (%)</i>		<i>Impregnation</i>
<i>Analytical plates</i>	<i>Preparative plates</i>	
0.5–2	1–5	Immersion Incorporation Spraying
5–30	5–20	
10–40	40	

of 30 µg. For preparative separation (0.5–1.0 mm layer thickness) the sample size can be scaled up to 80–100 mg, depending on the sample composition, the quantitative ratio between components and the required resolution.

Development

Most separation protocols recommend ascending development in covered tanks in which the atmosphere has been saturated with the vapour of the mobile phase. The saturation is considered to shorten the duration of development and often to improve the reproducibility. There are no firm data to support this conclusion and it might depend on the nature of the analyte. Poor separation and tailing of zones have also been reported under these conditions. Excellent separations of fatty acids and triacylglycerols are obtained without saturation of the atmosphere, or even in an open container. The geometry and volume of the developing container can also affect the separation. Narrow rectangular tanks and a moderate volume of the developing solvent provide better resolution.

Ag-TLC plates are normally developed at ambient temperature, but some improved resolution of fatty acid isomers requires a temperature of -20°C . It is assumed that resolution improves because the stability of the Ag^+ complexes increase when the temperature decreases. This might be true, but the properties of the sorbent and mobile phase also change at low temperatures. The action of all three factors is probably responsible for the better separations.

Various solvents are used to give two or three component mobile phases. Some of those most frequently used for separation of fatty acids and triacyl-

glycerols are listed in Table 5. Plates are often developed more than once to improve resolution. The separation should start with the most polar phase and proceed, after drying between runs, with mobile phases of gradually decreasing polarity. In this way, highly unsaturated components are resolved first and do not move further with subsequent developments when the more saturated components are separated. Obviously, the separation will improve substantially if a continuous development can be applied. In a simple approach, which has been used for the analysis of fatty acids and triacylglycerols, the development proceeds in an open cylindrical tank where a fixed volume (4–15 mL) of the mobile phase has been added. As the mobile phase is eluted through the plate, it is permitted to evaporate from the upper edge. Resolution was very effective and excellent results have been reported including the separation of positional isomers of triacylglycerols. This open system is quite sensitive towards the laboratory environment but operates very well in skilled hands.

Detection

All detection reagents that are suitable for visualizing compounds separated on plain silica plates are, in principle, suitable for use with Ag-TLC, particularly when the percentage of silver ions in the layer is below 2%. Destructive procedures are used for location, for identification and, to some extent, for quantification purposes. The reagent can be introduced by spraying, by treatment of the plates with its vapours or by incorporating into the layer. Some of the most commonly used detecting reagents for lipids are listed in Table 6. Solutions of chlorosulfonic acid in acetic acid, ethanolic phosphomolibdic acid and antimony

Table 5 Examples of mobile phases used to separate fatty acids and triacylglycerols by Ag-TLC

Compound	Mobile phase composition, by volume	Development
Fatty acids with 0–3 double bonds	Hexane–diethyl ether, 90 : 10 or 80 : 20 Hexane–acetone, 100 : 4	One-fold development in closed tanks. One-stage development in open cylindrical tanks. <i>E</i> - and <i>Z</i> -monounsaturated fatty acids are clearly separated.
Fatty acids with 0–6 double bonds	First plate: hexane–diethyl ether, 90 : 10 Second plate: hexane–diethyl ether, 60 : 40	Fatty acids are separated on two different plates. Species with 0–3 double bonds are separated on the first plate. Polyunsaturated species are separated on the second plate.
Triacylglycerols with 0–6 double bonds	Hexane–diethyl ether–acetic acid, 94 : 4 : 2 Benzene–ethyl acetate, 9 : 1 Benzene–diethyl ether, 85 : 15 Hexane–diethyl ether, 80 : 20 Chloroform–methanol, 96 : 4 Hexane–acetone, different proportions	All components are separated on a single plate by one-stage development. These mobile phases are used for both analytical and preparative separations in closed tanks. Development in open tanks with specified volume of the mobile phase, see the example in Figure 4.

Table 6 List of frequently used staining reagents for detecting lipids in Ag-TLC

<i>Reagent</i>	<i>Comments</i>
25–70% sulfuric acid	A destructive reagent, usually applied by spraying as solution in ethanol. Spraying must be very thorough and even, especially if the plate is considered for densitometric quantification. Spots are detected by heating the plate at temperatures of 150–200°C.
3% aqueous solution of copper acetate in phosphomolybdic acid	Advantageous in that precoated plates can be immersed in the solution, thus providing an even staining. Spots are visualized by heating.
Sulfuryl chloride	A highly volatile destructive reagent that allows convenient treatment of the plate in a closed container. This treatment provides even staining when the plate is heated. Suitable for densitometric quantification of lipids.
Rodamin 6G, 2,7-dichlorofluorescein	Nondestructive reagents used for preparative isolation of material for further examination. Plates are sprayed with diluted (>1%) solutions of the reagents in acetone. Spots are detected by viewing under UV light. The isolated material is purified from the detecting reagent by elution through a small silica gel column.

perchlorate in chloroform have been used to detect terpenes separated by Ag-TLC.

Spraying is a rapid but inconvenient and quite hazardous operation and should be avoided if and when possible and replaced by treatment with vapours. Incorporation of the charring reagents into the layer should be performed with circumspection, since it may change the nature of the resolution.

For preparative purposes, after detection, the separated zones are carefully scraped from the plate and the compounds are extracted from the sorbent with suitable polar solvents. As such material is likely to be subjected to further analysis, the extracts should be purified first. For example, in lipid analysis, excess silver ions and 2,7-dichlorofluorescein can be removed by passing the extract through small silica columns or by washing with bicarbonate, ammonia or sodium chloride solutions.

Identification

An advantage of Ag-TLC is the easy identification of the separated components with a substantial degree of certainty. A reference compound, or reference mixture of compounds, is usually applied beside the sample. The reference and the sample are developed simultaneously and this allows the migration distances (the R_F values) to be compared. Fatty acids and triacylglycerols form, for example, mixed zones with the matching reference components. In case of ambiguity, preparative Ag-TLC is applied to isolate and collect the component(s) in question for subsequent spectral analysis.

Quantification

As in all TLC techniques indirect and direct approaches for quantification have been employed. The most widely used procedure involves scraping off the detected zone and eluting the component(s) with suitable solvent. Then any of the available chromatographic or spectral techniques for quantification can be applied. Scanning densitometry can be used to measure the quantities of the separated compounds after a carefully chosen staining procedure. Staining is required since even UV-absorbing or UV-tagged compounds have either a very weak, or even no, signal in the presence of Ag^+ in the layer. Procedures have been reported for reliable densitometric quantification of fatty acids and triacylglycerols without the need for calibration graphs and correction coefficients, for example. **Figure 2** presents the densitometric profile of a triacylglycerol mixture separated by Ag-TLC.

Interactions in Argentation TLC

The rules of complex formation, presented above, have been found to be generally valid in the majority of separations performed by Ag-TLC. In many cases it is possible to predict the migration order. Interaction of Ag^+ with compounds that have more than two double bonds, however, seems to be less well understood. This primarily concerns lipids. A mixture of fatty acids, for example, may comprise components of different chain length (from 12 up to 22 carbon atoms) and of zero to six double bonds in the

Figure 2 Densitogram of olive oil triacylglycerols separated by Ag-TLC. Conditions: laboratory-made 5 cm \times 20 cm glass plate, 0.2 mm thick silica gel layer impregnated with 0.5% methanolic silver nitrate (by dipping); sample size: 20 μ g; mobile phase: 6 mL light petroleum–acetone–ethyl acetate, 100 : 3 : 2 (by volume); one-stage development in an open cylindrical tank; detection: successive treatment with bromine (30 min) and sulfuryl chloride (30 min) vapours followed by carbonization by heating at 180–200°C on a temperature-controlled hot plate; scanning: Shimadzu CS-930 densitometer in zigzag mode; beam dimensions: 1.2 mm \times 1.2 mm; working wavelength: 450 nm. Peak identity: Poly, minor components, containing octadecatrienoic fatty acid; the figures indicate the number of double bonds in the acyl residues but not their position in the glycerol backbone.

chain. Double bonds can be either *cis* (*Z*) or *trans* (*E*) or both and can have different position in the chain. Triacylglycerols and glycerophospholipids are complex mixtures of species that differ in the type and position of the acyl residues. So far, there are no theoretical or experimental studies on the mechanism of complex formation between Ag^+ and complicated unsaturated molecules. Almost nothing appears to be known about the electronic and steric effects in these molecules and their possible influence on complexation.

Attempts have been made to present the complexation of lipids in Ag-TLC in quantitative terms. Estimation has been made on the basis of the chromatographic retention of different molecular types. For example, arbitrary values of 0, 1, 2 + 2*a* and 4 + 4*a*, where $a < 1$, have been proposed for the complexing power of stearic, oleic, linoleic and linolenic fatty acids (with 0, 1, 2 and 3 double bonds, respectively). Evidently, the increase in the complexing power values is greater than the increase in the number of double bonds. More accurate equations have been proposed but, in general, the values are

close to those determined earlier and confirm the above conclusion. It has also been assumed that the respective values for the tri- or diacylglycerols can be expressed as a simple sum of the values for the fatty acyl residues. The assumption considers that the contribution of a fatty acid in a complex lipid molecule is not affected by the strength and properties of the silver ion complexes with neighbouring fatty acids in the same molecule. Such models are too simple and do not take account of the steric factors that may especially affect the complexation of a triacylglycerol molecule.

The role of the support material must be also taken into account. The most widely used support, silica gel, possesses appreciable polarity and absorption activity. Therefore, the retention of unsaturated compounds cannot be ascribed to the complexation reaction with Ag^+ and double bonds only, although clearly that is a major factor. The retention of an unsaturated molecule in any such system is the result of a mixed retention mechanism. For example, an unsaturated fatty acid methyl ester has been assumed to complex with the silver ions through its double bond(s) and to interact with the silanol moieties through its methyl ester group. Depending on the position of the double bond, the molecules will have different conformations. Those molecules may be held more strongly when the distance between the double bond and the ester group has a better fit with the distance between the silver ion and the silanol moiety. These two interactions have been suggested in explanation of the specific migration patterns of positionally isomeric fatty acid methyl esters. A mixed retention mechanism should be taken into account in the case of unsaturated compounds with other polar functional groups which are subjected to Ag-TLC.

A separate but related problem is the topology of silver ions on the adsorbent surface. For example, it was found that part of the silver nitrate remained in crystalline form, filling the pores of the silica gel after drying the plate to make the layer active. However, a proportion of the silver nitrate remained dissolved in the water, which is always bound to silica gel. The aqueous silver nitrate was assumed to be responsible for complex formation. Saturation of the silica layer with water before separation has even been proposed in order to obtain a pure complexation reaction. If the excess silver nitrate does indeed remain in a crystalline form and does not take part in complexation, impregnation of the layer with a highly concentrated solution of silver nitrate is of no practical value. Some of the results obtained with Ag-TLC seem to confirm this observation.

Retention and Resolution of Unsaturated Compounds in Ag-TLC: Examples

In general terms, acyclic unsaturated compounds migrate and can be resolved by Ag-TLC depending on the number, configuration and, occasionally, on the position of the double bond in the molecule, the number of the double bonds being the governing feature. The separation of fatty acids and triacylglycerols illustrates very well the resolution ability of Ag-TLC.

The migration pattern of fatty acids with zero to six double bonds is presented in Figure 3. For qualitative purposes it is possible to resolve fatty acids with unsaturation in the above interval on a single 5 cm × 20 cm plate using two solvent systems in sequence. Migration cannot always be predicted in the case of a mixture of fatty acids of different chain lengths. According to the general rules, when chain length increases, stability of the complex with silver ions decreases. This means that longer chain fatty acids will migrate ahead of shorter chain species of the same unsaturation (note the place of docosatetraenoic, 4a, and of octadecatetraenoic, 4b, fatty acids on Figure 3). The migration order of triacylglycerols follows the same rules, i.e. species with up to nine double bonds and acyl residue chains of 16–18 carbon atoms are ordered according to the increasing retention: 000, 001, 011, 002, 111, 012, 112, 003, 112, 013, 113, 222, 023, 123, 223, 133, 233, 333 (the figures indicate the number of double bonds in the acyl moiety but not their position in the molecule). It should be noted that of two species with an equal number of double bonds that in which all (or most) of the double bonds are concentrated into one fatty acyl moiety is held more firmly (011 and 002, for example). The separation of natural triacylglycerol mixtures depends strongly on the quantitative proportions between the components. For example, a mixture of components with relative high saturation can be resolved on a single TLC plate by the successive use of two mobile phases of decreasing polarity as illustrated in Figure 4. For satisfactory resolution of plant triacylglycerols with up to nine double bonds three different plates and two-stage development of each plate with mobile phases of different polarity is required. The approach provides accurate identification and densitometric quantification of the separated species.

E- and *Z*-isomers are normally easy to distinguish. An example of the separation of a fatty acid mixture is shown in Figure 5. Argentation TLC is may be the easiest and cheapest way to determine *trans*-monoenes in dietary fats.

Figure 3 Migration pattern of fatty acid methyl esters with zero to six double bonds in Ag-TLC. Conditions: laboratory-made 5 cm × 20 cm glass plate, 0.2 mm thick silica gel layer impregnated with 0.5% methanolic silver nitrate (by dipping); mobile phase: 5 mL light petroleum–acetone–formic acid, 97 : 2 : 1 (by volume); one-stage development in an open cylindrical tank; detection: as in Figure 2. Spot identity: the figures indicate the number of double bonds; 4a, methyl docosatetraenoate; 4b, methyl octadecatetraenoate.

Under specified conditions Ag-TLC differentiates between mono- or diunsaturated fatty acids with different position of the double bond(s) in the carbon chain. In 1970 Gunstone and colleagues supposed

Figure 4 Migration pattern of coffee triacylglycerols. Conditions: laboratory-made 5 cm × 20 cm glass plate, 0.2 mm thick silica gel layer impregnated with 0.5% methanolic silver nitrate (by dipping); sample size 50 µg; two-stage development with 4 mL light petroleum–acetone, 100 : 4 (by volume) followed by 15 mL light petroleum–acetone, 100 : 4 (by volume); detection: as in Figure 2. Spot identity: the figures indicate the number of double bonds in the acyl residues but not their position in the glycerol backbone.

that this is due to the participation of the fatty acid molecule in additional reaction(s) with either the silver ions or with the adsorbent. Reliable resolution was achieved in isolated cases only. The approach

was therefore of hardly any practical value until recently, when it was shown that separation depends strongly on the nature of the ester moiety. The effect is demonstrated in Figure 6 and has been assigned to the participation of the ester group and the double bond in simultaneous complexation with a silver ion to give a chelate-type complex.

Of practical value is the resolution of triacylglycerols that differ by the position of the unsaturated fatty acid residue in the triacylglycerol molecule (Figure 7). Since the position of acyl residues is strictly specific in natural triacylglycerol mixtures, Ag-TLC provides an easy way to distinguish between natural and modified edible fats and oils and the approach is of value to the food industry.

Conclusion

Ag-TLC is a valuable qualitative and quantitative method for the separation of unsaturated compounds, lipids in particular. Ag-TLC has the advantages of rapidity, simplicity and versatility and does not require expensive instrumentation. The information obtained reflects the whole sample, thus helping the analyst to make rapid, correct and efficient judgements. It is widely used as a preliminary step in combination with other chromatographic techniques such as GC and HPLC. Sufficiently pure

Figure 5 Migration pattern of *E*-, *Z*-fatty acid methyl esters. Conditions: laboratory-made 5 cm × 20 cm glass plate, 0.2 mm thick silica gel layer impregnated with 0.5% methanolic silver nitrate (by dipping); two-stage development with 2 mL light petroleum–acetone, 100 : 2 (by volume) followed by 3 mL light petroleum–acetone, 100 : 0.7 (by volume); detection: as in Figure 2.

Figure 6 Migration pattern of mono-unsaturated octadecenoic fatty acids differing in the position of the double bond in the carbon chain. Sample: aniseed oil. Conditions: laboratory-made 5 cm × 20 cm glass plate, 0.2 mm thick silica gel layer; detection: as in Figure 2. (A) Separation of the fatty acid as methyl esters. The layer is impregnated with 1% methanolic silver nitrate (by dipping); development is in an open cylindrical tank with light petroleum-acetone, 100 : 5 (by volume) at -20°C . (B) Separation of the fatty acids as phenacyl esters by two-stage development in a closed cylindrical tank (no preliminary saturation of the atmosphere) with a mobile phase of chloroform-acetone, 100 : 0.25 (by volume) at ambient temperature. Note the improved resolution achieved after conversion of the fatty acids into phenacyl esters. Spot identity: S, saturated fatty acids, V, vaccenic acid, 11-18 : 1; O, oleic acid, 9-18 : 1; P, petroselinic acid, 6-18 : 1; D, linoleic acid, 9, 12-18 : 2 (position of double bond-number of carbon atoms : number of double bonds).

components can be collected for further structural elucidation by spectral methods. Combined with scanning densitometry, Ag-TLC meets all requirements of a reliable quantitative method for determination of positional and configurational fatty acid isomers and of triacylglycerols in natural samples.

The resolution power of Ag-TLC will undoubtedly increase if and when an automatically controlled

Introduction

Salt has been a part of human existence since time immemorial. It was used for cooking wheat and barley as early as 5000 BC. The first salt was gathered from shallow lagoons where seawater could evaporate. Later rock salt was mined, and in the Alps, for instance, rock salt is known to have been mined as early as 1400 BC. Because of its importance to human life, salt has had an influence on economy, history and culture. Many sayings and words are derived from the use of salt: e.g. ‘to be worth one’s salt’ is a compliment, the Bible speaks of ‘the salt of the earth’ and soldier is derived from the Latin ‘*sal dare*’ which means to give salt.

Indeed, in ancient times salt had a much greater value than it has nowadays. It was traded weight by weight with gold, and the salt trade was very profitable. The Hanseatic League started by trading in salt. Taxes on salt were very common, and in that sense salt has played a role in many important historic events. The French Revolution was partly in protest against salt taxes. Gandhi’s campaign of civil disobedience, which eventually led to the independence of India, started when he evaded the British salt monopoly by producing salt himself.

Uses of Salt

Before the industrial revolution and the discovery of the electrolysis process, the uses of salt were limited.

The main uses were for the cooking, preserving and pickling of food and the tanning of hides. These uses are still very important, as salt is essential for the human body. With the development of chemical processes the uses of salt have diversified enormously. Apart from uses in the food industry, salt is, for instance, used in dyeing, paper production, highway de-icing, oil well drilling and the production of soda ash. Electrolysis of salt is the major source of chlorine and sodium hydroxide for the chemical industry. Chlorine is essential for the production of a number of plastics, insecticides and pharmaceutical compounds. Either directly, or in the form of derivatives, salt finds application in more than 14 000 ways. This multitude of applications can be divided into three major categories: chemical uses, highway de-icing, and food-related uses. In the industrialized nations the chemical industry accounts for approximately 50% of the salt consumption, and highway de-icing for about 30% while food applications make up the remainder. In developing countries most of the salt produced is used in food.

Production of Salt

As salt is the most abundant nonmetallic mineral, most countries have the ability to produce salt. It is so abundant that it is hard to estimate salt reserves. In the United States alone, reserves are estimated at 55 trillion tonnes. In 1996, 192 million tonnes of salt were produced, approximately 55% in the industrialized nations and about 45% in developing countries. Details are given **Table 1**.

Table 1 World production of salt in 1996

Country	Amount produced (in millions of metric tons)
United States	42.9
Peoples' Republic of China	28.9
Canada	12.3
Germany	10.9
India	9.5
Mexico	8.5
Australia	7.9
Other	71.8
Total	192.0

Salt is a cheap commodity. At a 1997 price level of US \$60 per tonne for chemical grade, merchant-delivered salt and US \$10 per tonne for captive use, salt is cheaper than any other refined chemical. Because of the low price of salt relative to the transportation costs, most salt production plants are in the vicinity of salt users. Producing an acceptable grade of purity at the lowest deliverable costs is the most important consideration for salt producers throughout the world.

How the salt is produced depends very much on the form in which the salt is available. In subtropic, arid regions salt is mostly produced by evaporating seawater. Large production facilities for so-called solar salt can be found in India, Australia and Mexico. In temperate regions, where the climate is less favourable for the evaporation of seawater, rock salt is mined. This can be done in two ways. Provided the salt deposit is close to the surface, it can be mined in the classical roof and pillar method. The rock salt is crushed, sorted and sold as a low grade quality. For more demanding applications further purification is needed. If the salt deposits are more deeply located, the solution mining technique is used. This involves pumping water down through a borehole to dissolve the salt, and recovering the resulting brine. The brine is then purified to remove foreign ions, and evaporated. The salt produced in this way is known as vacuum salt.

Fundamentals of Salt Crystallization

Salt or sodium chloride can occur in two forms. The first and best known form is the anhydrous form, NaCl. The second form is the dihydrate which is formed in a pure brine at temperatures below 0.1°C. The solubility of the dihydrate form is weakly temperature dependent, whereas the solubility of the anhydrous form is nearly temperature independent. The temperature dependence of the solubility of salt in water is given in Figure 1.

The anhydrous form, NaCl·0H₂O, crystallizes in the *Fm3m* space group in which each sodium ion is octahedrally coordinated by six chloride ions, and vice versa. The {1 0 0} faces are the slowest growing faces, resulting in the typical cube shape of salt crystals. By adding additives the {1 1 1} faces can be retarded, thus yielding octahedral shapes. Additives such as Fe (CN)₆⁴⁻ or NTAA (nitrosyl triacetamide) poison the {1 0 0} surfaces, resulting in preferential growth along edges and on corners. These shapes are given in Figure 2, together with a number of intermediate shapes where both cubic and octahedral faces are visible.

As mentioned before, salt is very soluble in water, so the growth rate of salt crystals is diffusion controlled. Like many other very soluble salts, the driving force needed to obtain acceptable growth rates (in the order of 10⁻⁸ m s⁻¹) is low, typically of the order of 0.1% or lower. Salt crystals produced in a forced circulation crystallizer (the most common type used for salt crystallization) typically have a mean size of 350–400 µm. In draft tube baffled (DTB) type crystallizers salt crystals can become larger, in the order of 500–1000 µm. Apart from the influence on the mean crystal size, the low driving force for crystallization also strongly reduces agglomeration. Agglomerated salt can only be obtained using techniques such as antisolvent crystallization where high driving forces are involved. There are three mechanisms for the incorporation of impurities in the final crystalline product. The first is direct incorporation of the impurity in the crystal lattice, the second is the formation of inclusions and the third is insufficient washing of the crystals.

In contrast to organic crystals, and to a lesser extent hydrated salt crystals, the ions are densely packed in the crystal lattice. This effectively prevents the incorporation of larger molecules in the crystal lattice as the lattice strain and the enthalpies involved are extremely unfavourable. This applies to many ions that have marked differences in ionic radius or charge from either the chlorine or sodium ion. The

**Figure 1** Solubility of NaCl in water.

Figure 2 Different crystal forms observed during the crystallization of common salt. Reproduced with permission from Elsevier Science.

tendency of salt to form solid solutions is therefore very limited. The only notable exception is with the incorporation of bromide, which is therefore very hard to remove as an impurity, once incorporated.

The second mechanism, the formation of inclusions, is much more common. In industrial crystallization the solid fraction in the slurry is high and therefore collisions between crystals are frequent. If the energy involved in a collision event is high enough the corners of the cubic salt crystals will be damaged and the crystals will be strained. Regrowth of these damaged corners is often imperfect and inclusions are formed. An effective method of reducing the impurity uptake through this mechanism, though at the cost of production capacity, is to lower the solids fraction of the slurry. It should be noted that this mechanism only occurs when large crystals are produced. If the crystals are small the kinetic energy involved in the collisions is not high enough to damage the crystals.

Good washing of the crystalline product is very important for the final purity. By evaporating water not only is salt produced, but the impurities are also concentrated. Any mother liquor that remains will therefore have a profound detrimental effect on the product purity. More impure mother liquors require better washing. This is more important for solar salt than for vacuum salt. Vacuum salt is produced from purified brine that contains, apart from NaCl, few very soluble salts, so despite incomplete washing the amount of impurities will still be relatively low. Concentrated seawater, in contrast, also contains high concentrations of very soluble salts, especially mag-

nesium salts. Insufficient washing therefore has much more influence on the product purity. Another important aspect when washing solar salt is the agglomeration.

A striking example of the influence of agglomeration on the final product purity is provided by the antisolvent crystallization of NaCl. Though the crystals are crystallized from a mother liquor containing as much as 50% weight antisolvent (on a solvent basis) the uptake of the antisolvent is as low as 30 ppm. Diluting the antisolvent stream with water, which reduces the driving force for crystallization, should result in a decrease in the impurity concentration. However this effect is offset by the increased agglomeration of the system, so instead of the expected lowering of concentration the concentration of antisolvent is increased to 100 ppm.

Irrespective of the method by which salt is produced, seawater is the source of salt (salt deposits are the result of natural solar salt production). The impurities present in brine or rock salt are therefore the same. These impurities are mainly Ca^{2+} , Mg^{2+} , Sr^{2+} , Br^- and SO_4^{2-} . All these impurities have undesirable effects on the electrolysis of sodium chloride and need to be removed during the production process. During electrolysis calcium, strontium and magnesium are deposited as hydroxides on the electrodes, which is of course not desired. The presence of Br^- leads to the formation of ClBr , which is also unwanted. Finally the presence of sulfate increases the cell potential needed for electrolysis, thus increasing production costs. A further impurity is iron, which is not only present in the salt, but is also added in the form of ferrocyanide, an anticaking agent. Though needed for proper salt handling, the presence of iron interferes with the membrane electrolysis. The ferrocyanide must therefore be decomposed and the iron precipitated as the hydroxide salt prior to electrolysis of the sodium chloride solution.

The strategy for removing these impurities depends on the production method. For solar salt production fractional crystallization combined with careful washing is employed, whereas in vacuum salt production the brine is purified prior to crystallization of the sodium chloride. In the rock salt production various recrystallization methods are used.

Solar Salt

Crystallization sequence Seawater contains nearly all elements of the periodic system in varying amounts. The composition of seawater is given in Table 2. When seawater is evaporated many different salts will be formed, at different stages during the evaporation. In that sense production of pure sodium chloride from seawater somewhat resembles

Table 2 Composition of seawater

Component	Amount present (g per 1000 g seawater)
Ca	0.408
SO ₄	2.643
Mg	1.265
Cl	18.95
K	0.380
Na	10.48
Br	0.065
Total	34.19

the distillation of crude oil, where one is interested in obtaining well defined fractions. When seawater is concentrated gradually iron oxide and calcium carbonate start to crystallize first, but the amount of iron oxide produced is negligible. Then calcium sulfate precipitates. It is important to note that when sodium chloride is subsequently crystallized, the mother liquor is concentrated with respect to both of the salts mentioned. After crystallizing about 75% of the available sodium chloride (at which stage 97% percent of the water has been evaporated), sodium bromide will start to crystallize as a solid solution with sodium chloride, and the so-called bitterns will also crystallize. The term bitterns is used for a collection of magnesium, potassium, sulfate and chloride salts, such as KCl, MgCl₂, MgSO₄ and double salts. It

is derived from the bitter taste of these salts. The whole sequence is depicted graphically in Figure 3. This figure shows the relationship between the density of the brine expressed as degrees Baume ($^{\circ}\text{Be} = 145 - (145/\text{specific density at } 15.6^{\circ}\text{C})$) and the crystallization of the various salts. The concentration factor can be deduced from the cumulative amount of water evaporated, which is also given in the figure.

Plant layout To produce pure salt, the crystallization of iron oxide, calcium carbonate and calcium sulfate must be physically separated from the sodium chloride crystallization. This is achieved in solar salt works by having two kinds of ponds: concentration ponds and crystallizer ponds. Approximately 90% of the water must be evaporated before salt starts to crystallize, so the concentration ponds are much larger than the crystallizer ponds. Though the water is not completely evaporated in the crystallization section (the brine is discharged before the bitterns start to crystallize), the concentration pond/crystallizing pond area ratio is usually around 10 to 1. Evaporation is a slow process, so solar plants must occupy a large area. The solar salt plants in Australia and Mexico, which supply the chemical industries in Japan and the United States, are tens of square kilometres in size. The seawater needs to be concentrated in stages so most solar salt plants have 5–10

**Figure 3** Deposition of salts during the evaporation of sea water at 25°C.

concentration ponds in series. These ponds are shallow to obtain the best surface area/volume ratio, with the depth usually between 50 and 80 cm. Small, low levees separate the different ponds. The crystallizer ponds are smaller, ranging from several hundred square metres in the case of manual harvesting to several acres in the case of mechanical harvesting. After harvesting the salt is transported to the washing plant. An example of the layout of a solar salt plant is given in Figure 4.

Solar salt production The need for large shallow ponds in the vicinity of the sea determines where solar salt plants can be operated. Small plants can be found in all coastal areas near the tropics, large plants only in India, Australia and Mexico. Such plants are operated all year round. Further north than the tropics, in arid areas as far north as western France, the operation is seasonal; the salt is harvested before the winter rains dissolve the salt produced.

Production of solar salt is started by taking in seawater. The seawater is concentrated by evaporation and the brine is reduced to about 60% of its original volume. After the first concentration stage the brine is transferred to another area where calcium carbonate starts to precipitate. Here a further 15% of the original volume is evaporated and the brine is

transferred to a third type of pond, the gypsum precipitation pond. The brine is concentrated to the point at which sodium chloride nearly starts to crystallize before it is transferred to the pickling pond where the brine, now saturated with sodium chloride, is kept before being transferred to the crystallizer pond. This pond is needed to reduce the gypsum supersaturation in the brine. At this point about 90% of the water has been evaporated. In the crystallizers, depending on the required purity, 70–75% of the available sodium chloride is crystallized before the remaining bitterns are discharged. Production of high quality solar salt is very much a question of knowing when to start producing halite and when to stop.

A major concern is the sealing of the ponds to prevent losses. It is impossible to treat the bottom of the ponds because of their large size, so the ponds must have a base such as clay, which is (fairly) impervious to water. The precipitated calcium carbonate (and also gypsum) will improve the sealing during operation so the losses will go down with time. By regularly changing the brine flow through the plant, all concentration ponds will be used as calcium carbonate and gypsum precipitation ponds, thus ensuring minimum brine losses (provided of course that the ponds are equal in size). Note that this is only possible in small plants.

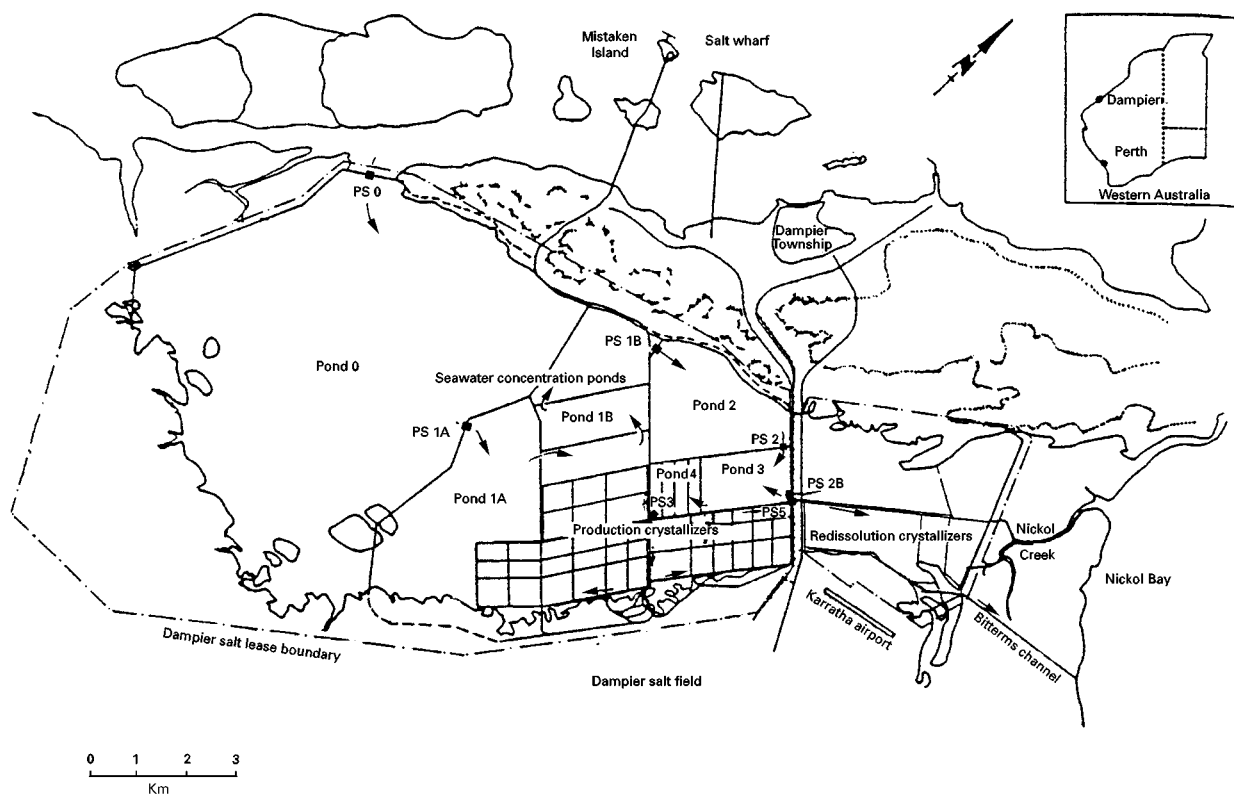

Figure 4 Schematic diagram of Dampier salt field layout and location map of Western Australia. Reprinted from Garrett DE, with kind permission from Elsevier Science Ltd.

The transmission of solar light in the brine is high, which reduces the evaporation rate. To enhance sunlight absorption dyes are added. The most common practice nowadays is to add algae which reduce the light transmission from 96% to 55–70%. An additional advantage is that the algae mats will also plug the pond bottom. Care must be taken not to increase the viscosity too much through abundant algae growth, or other organisms have to be introduced to keep the algae concentration within limits. Red halophilic bacteria are added to the crystallizing ponds for the same purposes.

The rate at which water evaporates depends on the climate. The amount of sunshine, the mean temperature, the relative humidity, the wind velocity and the average amount of precipitation determine the net evaporation rate. Accurate figures for the net evaporation are needed both for design purposes and for process control (read brine management). For design purposes climate data (incorporating amount of sunshine, air temperature and humidity and wind velocity) and brine data are taken into account. The gross evaporation rate can then be calculated by multiplying the difference in vapour pressure between air and brine by a mass transfer coefficient. In this mass transfer coefficient factors such as temperature, net gain of radiant energy and the heat transfer coefficient are taken into account.

For production purposes another model is generally used. The evaporation of water from a fresh water pan, situated on the site, is measured. This figure is then corrected for the salinity, the size of the pan and the rainfall.

$$\begin{aligned} \text{Evaporation (pond)} = & (\text{evaporation (pan)} \\ & \times k_{\text{scale}} \times k_{\text{salinity}} - \text{rainfall}) \\ & \times \text{area} \times \rho_w \end{aligned}$$

Here k_{scale} and k_{salinity} the scale factors and ρ_w is the density of water. Using this method it is possible to estimate how much has been evaporated from each pond, to decide when to pump brine from one pond to another, to take in sea water, etc.

In the crystallizer ponds a salt floor is formed during the crystallization of sodium chloride. The salt is harvested by completely removing the salt floor (in seasonal operations) or scraping the top layer (in year round operations). When the salt is mechanically harvested great care should be taken that the floor is strong enough to accommodate heavy equipment. Usually salt floors for mechanical harvesting are at least half a metre thick.

After harvesting the salt is washed by mixing the crystals with fresh saturated brine, and transferred to

a mesh conveyor where the brine is drained off. Generally sea water sprays are then used to finish the washing process. Provided the washing is carried out very thoroughly, and the crystals are crushed to remove the mother liquor contained in cavities, solar salt can reasonably pure, though not as pure as vacuum salt. In most cases solar salt contains significantly more magnesium (300–500 ppm), calcium (200–300 ppm) and sulfate (1000–1500 ppm) than vacuum salt.

The salt can be upgraded using the Salex[®] process. This process utilizes the difference in density and morphology between sodium chloride and other minerals. The salt crystals containing the impurity crystals are countercurrently washed with a saturated brine. The salt crystals settle, and the impurity (mainly gypsum) crystals are carried away with the brine and left to settle in a separate tank. The clarified brine can then be reused. By leaving the produced salt piles exposed to rain, impurities will preferentially dissolve, thus improving the salt quality. This is called the rain wash method.

Rock Salt

Provided the rock salt deposits are close to the surface, rock salt can be mined in the classical way. First a vertical shaft is dug until the salt bearing deposit has been reached. Then horizontal shafts are blasted and the salt thus produced is transported to the surface. For de-icing use the salt is only crushed and sorted by size. For chemical applications the rock salt must be upgraded. This can be achieved in several ways. First of all, the rock salt can be completely dissolved. The resulting brine is then treated in the same manner as brine obtained by solution mining. As this process is more expensive than solution mining it is hardly ever used. The second option is to recrystallize the brine by making use of the fact that sodium chloride also has a hydrated solid phase.

This process works as follows. First small, crushed salt crystals are suspended in a brine at a temperature of 5°C. The brine is then cooled to a temperature lower than 0°C. At this temperature NaCl is more soluble than the hydrated phase, NaCl·2H₂O. The anhydrous sodium chloride crystals will dissolve and sodium chloride dihydrate crystals will be formed. When the slurry now containing the dihydrate crystals is heated, the process is reversed. The dihydrate crystals will dissolve and anhydrous crystals will be formed. During the two consecutive crystallization steps the impurities present in the dissolving crystals will remain to a large extent in the brine, instead of ending up in the new crystals formed. Using this method, the purity of the salt can be markedly improved without having to evaporate the brine. After the recrystallization steps the now purified

crystals are separated from the brine and the brine is reused after treatment.

Vacuum Salt

Brine purification Vacuum salt is the name given to salt produced by evaporative crystallization. Water is injected into a salt deposit through a borehole, and dissolves the salt so the resulting brine can be recovered. This brine is then purified before salt is produced by evaporative crystallization. The deposits used for this kind of salt production lie at depths between a few hundred and three thousand metres. Two pipes are used, one bearing fresh water to the cavern, the other transporting brine to the surface. Because of surface subsidence and ground movements, the caverns cannot get too large. Normally the size is smaller than 100 m in width. Furthermore, above the cavern a layer of a few metres of salt must be maintained to protect the overlying strata from brine penetration. Once the cavern has reached its maximum allowable size, solution mining is stopped and a new borehole is drilled.

It is interesting to note that the salt mined in such a way has already been crystallized once. All salt deposits are remains from earlier lakes and seas, which have been evaporated. Thus the salt is already separated from the calcium sulfate and bitterns originally present in the seawater.

Though already purer than the saturated brine produced by seawater evaporation, the brine produced still contains significant amounts of calcium, magnesium, sulfate and bromide ions. Most of these ions are removed in the brine purification process. First the sulfate is removed by adding calcium oxide, which leads to the precipitation of gypsum. The oxide increases the pH of the brine, which induces the precipitation of magnesium hydroxide. Thus in the first stage sulfate and magnesium are removed. To reduce production costs this process is carried out using very simple equipment. Calcium oxide is simply mixed with the brine in a very large tank. To decrease the

supersaturation further tanks are used. The solids are removed by draining the tanks and emptying them.

A drawback to this procedure is the increased calcium level in the brine. To reduce this level gases from an on-site power plant are usually used. The carbon dioxide yields carbonate, due to the high pH of the brine, which together with calcium forms the almost insoluble calcium carbonate. Because of the high salt concentration and high temperature, vaterite is formed rather than the usual calcite. This is an advantage because strontium, which is also present in the brine, is also effectively removed as strontium carbonate forms a solid solution with vaterite.

Crystallization After purification the water is evaporated and salt is crystallized. To conserve energy this is done in several stages. Each stage is operated under a lower pressure so the brine boils at a lower temperature. The vapour produced by the previous stage condenses in a heat exchanger and as this steam was formed at a higher temperature, the brine starts to boil. In this way the steam used in the primary stage can be reused several times. This principle is shown in Figure 5. Thus the total amount of energy involved in the production of vacuum salt is greatly reduced. In a typical four-effect installation (see Table 3) the first effect operates at slightly elevated pressures while the other effects operate under reduced pressure, hence the name vacuum salt.

Generally salt crystallizers are of the forced circulation type with external heat exchangers. For a production of 1 million tonnes per year, a total crystallizer capacity of 800–1000 m³ is needed. The separate crystallizers can be operated in different modes. The salt produced can be separated from the mother liquor separately for each crystallizer, or the slurry can be transported from one effect to the other, thus increasing the solids content of the slurry in each successive stage. This has important implications for the purity. In the first case the salt produced in the first crystallizer is the purest. Little water has (yet)

Figure 5 Scheme of a four effect evaporative crystallization plant.

Table 3 Temperatures and pressures in a four-effect evaporative crystallization plant

Effect	1	2	3	4
Pressure (bar)	2.0	0.89	0.34	0.18
Temperature (°C)	120	96	72	58

been evaporated and the impurity concentration is low. In the successive crystallizers the impurities are gradually concentrated, which has a detrimental effect on the purity. Thus different grades of salt are produced.

When the slurry is transported from one effect to the other, only one grade of salt is produced, which represents the mean purity when compared with the other method. There will be local differences in purity, the centres of the 'oldest' crystals being the purest, whereas the newer crystals and the collision prone corners of the larger crystals will contain more impurities.

Brine recovery As with the production of solar salt, the amount of impurities determines when the crystallization is stopped. Again bromide is important in that respect, as it is very difficult to remove. One is then left with a brine containing valuable salt that unfortunately it is difficult to recover because of the high impurity content. Several procedures have been devised to cope with this problem. The first process, used by Akzo Nobel, is the Bromin process. In this process the remaining sulfate- and bromine-rich mother liquor is further evaporated in a separate crystallizer, where sodium sulfate is crystallized in addition to sodium chloride. The remaining, greatly reduced amount of mother liquor, now very rich in bromine, is discharged in a nonproductive borehole. Sodium chloride and sodium sulfate are added to the raw brine entering the brine purification. Sodium sulfate dissolves and the sulfate precipitates as calcium sulfate.

At the Salinen Austria GmbH production facility nearly the same procedure is used, but instead of crystallization of anhydrous sodium sulfate and sodium chloride, the company claims that sodium chloride and glaserite ($\text{Na}_2\text{SO}_4 \cdot 3\text{K}_2\text{SO}_4$) are formed. After washing with raw brine, the glaserite is dissolved and the sulfate serves to precipitate calcium while the sodium chloride remains behind.

Another method involves cooling the remaining brine, thus producing Glauber salt, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$. Subsequent evaporation of the mother liquor yields sodium chloride. The remaining brine is then discarded.

Introduction

Sample preparation is an important component of an analytical method. It is used to concentrate an analyte to improve its limits of detection, as well as to isolate an analyte from unwanted matrix components that can cause interferences upon analysis. Solid-phase extraction (SPE), as a tool for this sample concentration and isolation, has gained acceptance since its commercial introduction circa two decades ago. SPE is performed using commercial packed cartridges (containing approximately 50–500 mg packing material) as well as discs (containing from 4–500 mg). Many formats, chemistries and sizes of SPE products are available to meet a range of separation needs.

Solid-phase extraction is preferred to other types of sample preparation techniques, such as liquid-liquid extraction (LLE), for many reasons. SPE is an efficient technique, often achieving higher recovery of analyte than other methods of sample preparation because of its selectivity. The chemistry of attraction between an analyte and the solid sorbent can be exploited by pH and solvent considerations to allow interaction yet exclude interferences. SPE is a less time-consuming and labour-intensive technique. Extraction typically involves adding different liquids through SPE columns in parallel and collecting the eluate at the final step. Emulsion formation is eliminated – in LLE an emulsion sometimes forms between the aqueous and organic layers preventing phase separation. Organic solvent consumption is far less using SPE than typical LLE techniques, saving money in terms of both purchase costs of solvents and costs to dispose of these regulated solvents. Reduced exposure of the analyst to organic solvents also improves safety in the laboratory. Unlike LLE the SPE procedure using columns can be automated. There are several hardware choices available commercially that transform SPE from a manual procedure into a fully automated one, allowing the analyst to perform other tasks in the laboratory. Batch procedures of automation are available in which a number of samples are extracted to yield the same number of eluates ready for analysis.

On-line serial automation is common, in which a sample is extracted then injected by the instrument and, while analysis is ongoing, the next sample is extracted. Miniaturization of SPE allows the convenient use of smaller sample sizes and the ability to physically work with eluates as small as 50 µL when using the disc format.

The SPE technique has been shown to be useful for a variety of sample matrices, including (but not limited to): drinking water and river water, air, biological fluids (e.g., blood, serum, plasma, urine), tissues, peptides, drug formulations, microbial broths, animal feed, beverages, fruits and vegetables, and soil. Thus, the number of applications for this sample preparation technique in the literature is extensive and can be found spanning the last 25 years. It is the goal of this chapter to highlight many of the applications of SPE for a variety of sample matrices and demonstrate the versatility and usefulness of this sample preparation technique (Table 1).

Table 1 Examples of classical analytical applications using solid-phase extraction

<i>Market</i>	<i>Application</i>
Environmental	Trace enrichment of organic pollutants from water
	Organic acids, detergents and surfactants from water
	Insecticides and pesticides from soil
	Explosives residues in groundwater
	Oil and grease analysis
Food	Pesticides in fruits and vegetables
	Sodium benzoate in colas and fruit juice
	Plant growth regulators in spinach juice
	Toxic fungal metabolites in rodent feed
	Vitamins in food
	Cholesterol oxidation products in milkfat
	Caffeine in beverages
Biotechnology	β-Agonists and antibiotics in meat products
	Purification and fractionation of proteins and peptides
	Desalting of peptides
	Purification of DNA from microbial broths
Pharmaceutical	Antibiotic content in ointments
	Aspirin content in tablets
	Drugs in serum, plasma and urine
Clinical	Catecholamines in plasma and urine
	Lipids in serum
	Drugs in tissues
	Vitamins and steroids in serum
	Cyclosporin in blood

Environmental Applications

Trace Enrichment from Environmental Samples

The gas and liquid chromatographic analyses of polar pollutants in waters (e.g. for drinking, river and effluent) require a concentration step before analysis to determine part-per-million levels and lower, as regulations specify. Solid-phase extraction is the most widely used technique for trace enrichment of polar environmental pollutants since it uses low volumes of hazardous organic solvent, can be automated using cartridges and discs, and the analysis can be done either off-line in batches or on-line with the chromatographic system.

Typically, 1 L volumes of water samples are required for analysis in the United States, as mandated by the Environmental Protection Agency (EPA). Hydrophobic C18 and C8 sorbents are commonly used for the majority of trace enrichment needs; the analyte structure dictates the optimal sorbent chemistry. Practical considerations for passing 1 L of water through a SPE cartridge favour the use of larger diameter (47 or 90 mm) discs (e.g. glass fibre and PTFE-based) for these applications. While both discs and cartridges can be automated, discs are preferred for their much larger cross-sectional surface area. Using discs, liquid can be passed through at high flow rates without loss of analyte, thus reducing the extraction time to about 10–15 min instead of about 1 h for narrower cartridges.

Aqueous samples (100 mL to 1 L) containing organochlorine pesticides (e.g. lindane, methoxychlor, or endosulfan) can be concentrated from water, made acidic by using C18 bonded silica in 47 mm discs. Elution from the sorbent is accomplished using 3–5 mL aliquots of ethyl acetate, from which water is removed in a separate step using anhydrous sodium sulfate, it is then concentrated before analysis using gas chromatography (GC) with electron capture detection (ECD). Polyaromatic hydrocarbons (e.g. phenanthrene, pyrene, anthracene), organophosphorous pesticides (e.g. diazinon, methyl parathion), and herbicides (e.g. atrazine, alachlor) may be analysed in a similar manner using C18 sorbent and ethyl acetate elution from discs prior to GC analysis.

Phenols and chlorinated phenols are moderately polar compounds that can display ionic character at pH values above 7. Another group of polar compounds displaying ionic character is the acid herbicides (e.g. 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid and dicamba). Rather than C18 bonded silica, a more efficient sorbent for extraction of these types of compounds is polystyrene divinylbenzene (SDB), an organic polymer. SDB has

a slightly different selectivity than C18, owing to its aromaticity, that allows it to extend its range of attraction to include more polar species such as phenols. Other advantages of SDB are that it is totally organic, is stable across the entire pH range, and has greater capacity per gram than comparable reversed-phase bonded silica sorbents. Extraction of these phenols is performed with a SDB disc (or cartridge). Elution from the sorbent is accomplished using 3–5 mL aliquots of acetonitrile (methanol or acetone may be substituted) before analysis.

Diquat and paraquat are examples of polar compounds that are quaternary amines, thus always positively charged. These analytes are found only in very small concentrations in water, since they more readily attract to soils and plants via their cationic functionality. They can be concentrated from water on a cyano sorbent or some types of C8 sorbent, those that have a high degree of residual silanols available for attraction of cationic species. The extraction method for C8 includes an ion-pairing agent, to which paraquat and diquat bind. Elution with 5 mL methanol containing acid and diethylamine disrupts this binding; analysis is by HPLC. Table 2 lists examples of USA EPA methods employing disc solid-phase extraction.

On-Line Techniques

While SPE is a successful technique performed in batch mode before the analysis step, there can be drawbacks such as loss of sensitivity (only an aliquot of the total mass isolated is used), losses due to evaporation or during transfer and contamination from external sources. Instrumentation has now advanced to allow for on-line trace enrichment, where the sample eluent is injected onto a high-pressure liquid chromatography (HPLC) apparatus. The sample can be isolated on a guard column while the HPLC is running the previous sample, so time is not lost between isolation and analysis. The cartridge performing the extraction on-line, coupled to a liquid chromatographic system, can be commercially bought, such as the PROSPEKT system (Spark Holland) or constructed by hand using Empore® (3M Company) membrane extraction discs placed into a holder (4.6 mm internal diameter). Multi-residue methods that extract a variety of pesticides (acidic, neutral and basic) from waters are commonly used. In order to preconcentrate all these compounds simultaneously, it is necessary in most cases to acidify the sample and use a C18 bonded silica or polymer-based SDB sorbent in series with a cation exchanger. In order to avoid rapidly overloading the cation exchanger with samples of high ionic strength, calcium ions are first precipitated

with oxalic acid and heavy metals are complexed with ethylenediaminetetraacetic acid (EDTA) prior to SPE. SPE cartridges on-line are sometimes preloaded with sodium dodecyl sulfate (SDS) to improve retention of basic pollutants at low pH.

Organic Acids Found in the Environment

The trace determination of EDTA in environmental water samples is an example of an analytical challenge – one in which the analyte readily chelates with metals, is very water soluble and is an organic acid. EDTA is commonly used in the clean-up of radioactivity and heavy metal wastes, and is also found in the environment as a detergent and water softening agent. Chelation of EDTA with toxic metals facilitates the migration of these hazardous materials from ground dumps into a water-soluble state where they can be transported into lakes, rivers and streams. The sample preparation technique of choice for EDTA is SPE since it improves detection limits compared with other techniques and can be fully automated. The lowest detection limits ($0.15 \mu\text{g L}^{-1}$, five times lower than previously reported methods using GC-mass spectrometry (MS) and HPLC) have been obtained using capillary electrophoresis (CE) with ion-spray

tandem mass spectrometry (MS-MS) for selective detection.

The sample preparation of EDTA from water samples (5 mL) involves conversion of all free and chelated EDTA present into the nickel EDTA chelate by adding $100 \mu\text{L Ni}(\text{NO}_3)_2$ at a pH from 7–9. The pH is then adjusted to about 3.0 using about $12 \mu\text{L}$ of 9% formic acid. This sample is added to preconditioned strong anion exchange solid-phase extraction cartridges (SPEC® (Ansys Diagnostics glass fibre disc cartridges). Wash solvents used (in order) are water (adjusted to pH 3.0 with formic acid), water (neutral pH), and methanol. Finally, the NiEDTA is eluted using a solution of 50 mM trifluoroacetic acid, 1 mM bromothymol blue and 5% methanol. The eluate is evaporated to dryness, reconstituted in 0.1% ammonium hydroxide, evaporated to dryness again, and then reconstituted in $30 \mu\text{L}$ water for analysis. This extract is then analysed by CE-MS. The strongly acidic elution solvent dissociates the NiEDTA complex, while bromothymol blue displaces the remaining NiEDTA from the disc. Reconstitution in ammonium hydroxide facilitates the re-complexation of the NiEDTA.

Food Applications

Pesticides in Food

Food applications using SPE present complexities that are not encountered in water extractions. Substances such as apples, lettuce, tomatoes and strawberries have tissue components that must be removed before extraction, and the analytes within the tissue fluids must be made available for extraction or removal prior to analysis. Multiple pesticides are commonly analysed in food crops. One popular multi-residue screening technique is the Luke II method, in which a crop sample (100 g) is homogenized with a water-miscible solvent (acetone). However, other crop materials that have solubility in acetone are also extracted. The solvent and water from the crop are then filtered and the filtrate subjected to a series of liquid-liquid partitioning extractions. The resulting mixture is subjected to two or more SPE packed cartridge (or disc) clean-up steps using sorbents with varying selectivity to remove co-extracted materials while pesticides pass through. Use of SPE techniques within this method allows for reduced solvent use and improved throughput.

A variation of this approach described uses SPE discs with reversed-phase sorbents (SDB-RPS disc stacked on top of a carbon disc; 3M Company) to capture the pesticides, rather than the co-extracted substances that often use normal-phase sorbents. This disc procedure is as follows. A 100 g sample of each crop material is mechanically blended with 100 mL acetone. The puree is filtered through a glass fibre filter and three 10-mL aliquots (10 g crop equivalent, wet weight) of each filtrate are transferred to centrifuge tubes, and the volume is reduced under nitrogen to about 5 mL. Water is added to adjust volume to 15 mL. SPE discs are conditioned with acetone, followed (in order) by ethyl acetate, methanol, then water. Samples are filtered through each disc. When the entire sample has been extracted, the discs are removed and inverted, so that SDB-RPS is on the bottom and carbon on the top. Elution is accomplished with 2 mL acetone, followed by two successive 5-mL aliquots of ethyl acetate. The eluent is dried using anhydrous sodium sulfate, then concentrated by evaporation to 5 mL volume, and analysed by GC-ECD. The combination of SDB-RPS and carbon sorbent chemistries for the extraction is superior to reversed-phase bonded silica sorbents to extend the range of attraction to the more polar pesticides with high water solubility, namely dimethoate, *o*-methoate and methamidophos. SDB-RPS contains the SDB chemistry but because of the nature of sulfonic acid groups bonded on the SDB surface it captures cationic moieties also. Carbon is used to capture

analytes not retaining on SDB-RPS. By reversing the order of sorbents for elution, the pesticides never come in contact with the carbon and are quantitatively recovered.

β -Agonists in Cattle Meat

β_2 -Agonists (e.g. clenbuterol, brombuterol, mabuterol and mapenterol), originally developed for treatment of chronic obstructive pulmonary diseases in humans, have been misused as a repartitioning agent in the fattening of cattle. When cattle are treated, residues may remain in the meat and liver. In order to monitor regulatory bans on use of these drugs in cattle, samples are removed at slaughterhouses and analysed for the presence of these illegal growth promoters. Urine is the matrix most commonly used for the analysis of these β -agonist drugs. Solid-phase extraction has been shown to be an effective technique for these drugs, using reversed-phase or mixed-mode sorbents (containing both reversed phase and cation exchange functionalities). The SPE procedure adds 1 mL 0.5 M potassium phosphate buffer pH 4.0 to 5 mL urine, followed by centrifugation. A mixed-mode sorbent bed is conditioned with methanol, water, then 0.1 M potassium phosphate buffer pH 4.0. The sample is loaded onto the cartridge, followed by a wash solvent of 70% methanol in water. After drying the cartridge, elution is accomplished with ethanol-*n*-hexane-ammonium hydroxide (70 : 25 : 5, v/v/v) in two sequential portions. Solvent is evaporated under nitrogen and heat and reconstituted in 25% acetonitrile in water for HPLC analysis.

Biotechnology Applications

Purification and Fractionation of Proteins and Peptides

Proteins are significant components of most physiological samples. It is often important to measure very low concentrations of specific peptides in biological fluids for diagnosis of disease states and to investigate physiological roles of certain peptides. Examples include examining the role of atrial natriuretic peptide in cardiovascular disease, studying β -endorphins involved in the neurochemistry of the brain, and isolating lymphokines to monitor their effect on immune system regulation. The quantification of a peptide such as casein in milk products is an application in the food area requiring isolation and purification. Solid-phase extraction is commonly used as a preliminary purification step to remove cross-reacting or interfering materials in sample matrices before analysis.

One common approach to purifying hydrophilic proteins or peptides is to fractionate crude proteinaceous extracts and remove hydrophobic proteins. Proteins above 15–20 000 molecular weight are usually too large and cannot easily enter the pores of typical 60–100 Å bonded silica particles. Thus, these large proteins pass unretained through reversed-phase sorbents and can be effectively eliminated from the analyte in this manner. The procedure is as follows. The sample is loaded onto the SPE column in an aqueous buffer, then washed with dilute aqueous acid (e.g. 0.1% trifluoroacetic acid, TFA) to remove salts and low molecular weight contaminants. Peptide analytes of interest are eluted with a mixture of organic solvent (acetonitrile or propanol) in water containing 0.1% TFA. The SPE sorbents useful for peptide retention, in increasing order of hydrophobicity, can generally be stated as cyano < C2 < phenyl < cyclohexyl < C8 < C18. Very polar peptides should be isolated using sorbents with a high retention ability such as C8 or C18. Very hydrophobic peptides could be isolated with a less retentive sorbent such as cyano or C2. Medium and highly hydrophobic peptides could be efficiently isolated and fractionated with phenyl and cyclohexyl sorbents.

SPE based on ionic interaction of proteins can efficiently fractionate peptide mixtures into neutral, acidic and basic pools. In ion exchange chromatography, adsorption of proteins depends on the protein's isoelectric point relative to the column pH. Proteins with a high isoelectric point will bind tightly to a cation exchange column in the presence of a low pH and a low salt concentration. Proteins with a high isoelectric point will bind tightly to a cation exchange column in the presence of a low pH and a low salt concentration. Proteins with a low isoelectric point will bind tightly to an anion exchange column in the presence of a high pH and a low salt concentration. Hydrophobic interaction chromatography uses a high salt concentration to induce an interaction between hydrophobic regions of a protein and a weakly hydrophobic column packing. In all three cases, elution of the bound proteins can be achieved using a salt gradient.

On-Line Preconcentration using SPE

The techniques of CE and on-line CE-MS have been widely documented for the analysis of therapeutically important peptides of diverse nature. A limitation of CE is that it works best for small sample volumes (typically < 50 nL for a 50 µm internal diameter capillary). This volume restriction leads to a poor concentration limit of detection (CLOD) when compared with typical HPLC and

LC-MS systems. The incorporation of a membrane preconcentration cartridge (containing SPE in a membrane format) in-line with the CE capillary has allowed the introduction of much larger sample volumes (e.g. 100 µL), lowering the CLOD. Typical materials used for the preconcentration are reversed-phase sorbents, such as SDB and C18 bonded silica. This technique has allowed the analysis of biomolecules present in complex matrices, such as proteins in aqueous humour.

Pharmaceutical Applications

Bacitracin Extraction from a Pharmaceutical Ointment

Bacitracin ointment, an oily pharmaceutical formulation, is a mixture of at least nine antibiotic polypeptide complexes. These peptides are very polar and soluble in water and ethanol, but not in acetone or hexane. They can be separated from the ointment base by adding chloroform to the sample matrix, and the polar peptide antibiotics are adsorbed to a polar diol SPE column. Upon addition of the matrix to the column, the nonpolar solvent and ointment products pass through. A wash of chloroform removes potentially interfering components of the formulation. Antibiotics are removed from the sorbent using 0.1N HCl; protons from the acid displace the drugs from the hydroxyl groups on bonded silica surface. This technique can be useful for other drug substances by optimizing the SPE conditions for the properties of the drug and excipients, and selecting the appropriate sorbent and eluent systems.

Analysis of Aspirin Content in Tablets

Aspirin can be analysed for content in tablets by using a mixed mode sorbent containing both anion exchange and reversed-phase characteristics. Polysorb MP-2 (Interaction) polymer is a cross-linked vinylpyridine. At low pH the polymer is protonated and exhibits anion exchange and reversed-phase properties. At high pH, the polymer is neutralized and exhibits only reversed-phase properties. The sorbent is conditioned with acid/organic 10/90 (v/v) to induce polymer ionization. After sample loading, the sorbent is washed with 20–50% acetonitrile/water to neutralize the sorbent bed prior to elution of bound aspirin. Elution is accomplished with acetonitrile 30% NH₄OH–30 mM diammonium sulfate monohydrate (6 : 2 : 1, v/v/v). The polymer becomes neutral at this basic pH > 12.9 and aspirin remains ionized, disrupting its interaction with the sorbent and eluting. Salt acts as counteranion to further assist in the elution of aspirin.

Clinical Applications

Catecholamines from Plasma and Urine

Catecholamines (e.g. dopamine, epinephrine and norepinephrine) are of clinical interest for their role in neurochemistry as diagnostic indicators of pheochromocytoma. These dihydroxylated amines are commonly analysed by HPLC with electrochemical detection. Many different SPE sorbents have been reported for their sample preparation. Alumina particles (about 50 mg) are added to plasma and buffer in a suspension, followed by centrifugation and subsequent elution from alumina. Reversed-phase C18 has also been used, as well as phenylboronic acid and strong cation exchange (SCX). The urine analysis of catecholamines examines metabolites such as vanillylmandelic acid and homovanillic acid. Typically, solid-phase extraction (SPE) uses SCX sorbent to provide cleaner chromatograms, either alone or in addition to alumina or phenylboronic acid.

Lipids

The extraction of lipids, including phospholipids, fatty acids, cholesterol, cholesteryl ester, and triglycerides in serum has been accomplished using polar SPE sorbents such as silica and aminopropyl. The sample matrix is extracted with a nonpolar solvent such as chloroform, and this extract is passed through a preconditioned polar aminopropyl sorbent for attraction of analytes by hydrogen bonding and weak ion exchange mechanisms. Neutral lipids are eluted with chloroform–propanol (2:1, v/v), fatty acids are eluted with 2% acetic acid in diethyl ether, and phospholipids are eluted with methanol. The neutral lipid fraction is evaporated and reconstituted in hexane. The hexane mixture is then passed through a second amino SPE column. The cholesteryl esters are eluted with hexane, with the second column in series with the first column to trap cholesterol, which elutes with triglycerides. Triglycerides are eluted with hexane–diethyl ether–methylene chloride (89 : 1 : 11, v/v). The two amino columns are separated and cholesterol is eluted from both – di- and mono-glycerides elute from the upper amino column. Cholesterol is eluted with 5% ethyl acetate in hexane, diglycerides are eluted with 15% ethyl acetate in hexane and monoglycerides are eluted with chloroform–methanol (2 : 1, v/v).

Drugs in Tissues

The majority of reported methods for drug extraction involve plasma, serum, urine or other polar fluids that can easily pass through SPE cartridges. However, blood and tissue extraction applications have not

been reported with much frequency in the published literature. The extraction of drugs from tissues, such as liver, kidney, intestine, brain, muscle and adipose tissue is important for the forensic toxicologist, in particular, since urine and blood are not available in post-mortem cases. Concentrations of drugs in tissues are also of great interest to researchers investigating the deposition of drugs in certain tissues (e.g. ophthalmic drug delivery into the eye and delivery of antidepressant drugs into the brain).

Drug extraction from tissues involves first homogenization of the tissue with aqueous solution. After homogenization, an enzyme digestion (e.g. Carlsberg subtilisin, lipase or protease) step and/or protein precipitation can be used, followed by centrifugation. Sometimes a small percentage (10–20%) of organic solvent (e.g. methanol) is added to the water or buffer for homogenization, and the solution is passed through an SPE cartridge. Alternatively, 100% methanol or acetonitrile can be used and, after centrifugation, the solvent is evaporated, reconstituted in aqueous solution or buffer, and passed through an SPE cartridge. In addition to typical SPE sorbents, diatomaceous earth is another choice for the analyst; it facilitates a liquid–liquid extraction by attracting analytes to the particles to increase surface area available for extraction when an organic solvent is passed through the diatomaceous earth column. The use of ‘high-flow’ SPE columns is now a reality owing to larger particle-size sorbents in columns, typically 100–120 µm particle sizes instead of 40–60 µm.

Conclusion

Solid-phase extraction has been demonstrated to be a reliable and cost-effective technique for the selective isolation and concentration of a wide range of analytes and sample matrices, and offers many improvements over traditional techniques such as liquid–liquid extraction. Some of the classic applications for SPE include environmental trace enrichment of organic pollutants, extraction of pesticides and growth promoters from foods, purification of peptides, drug analysis in pharmaceutical dosage forms and clinical applications for drugs in physiological matrices. Its ability to solve sample preparation problems has been well documented in the literature over the past two decades. There is a wide choice of sorbents for SPE, including nonpolar, polar, ion exchange and mixed mode chemistries, providing the analyst with the selectivity necessary to obtain clean extracts for analysis. SPE can be used either manually or with greater throughput using automated workstations. The introduction of new sorbents with more selective modes of attraction, novel product formats

such as the SPE disc, and the proliferation of automated techniques for performing the extractions, ensure that SPE will continue to be a preferred technique for sample preparation in many different analytical disciplines.

SOLID-PHASE EXTRACTION WITH DISCS

C. F. Poole, Wayne State University, Detroit, MI, USA

Copyright © 2000 Academic Press

Introduction

Solid-phase extraction is a well-established technique for the isolation, concentration and matrix simplification of analytes in samples with unfavorable properties for direct analysis by the best available approach. Extraction is achieved using a particulate sorbent packed into columns of short length (sometimes called ‘cartridges’) or immobilized in the form of a thin disc, referred to generically as ‘disc technology’. Since the same sorbent chemistry is used for the extraction step and liquid desorption for the elution step in both approaches, the two techniques differ only in format. On an evolutionary scale, solid-phase extraction using short columns was introduced as a laboratory-scale technique in the late 1970s and came to prominence in the 1980s. Disc technology, by comparison, was first introduced in 1989, and is still evolving as a competitive technique to short packed columns. Simply stated, disc technology should be viewed as an alternative approach to performing solid-phase extraction with additional benefits and capabilities derived from the difference in format. Whereas packed columns are easily prepared in the laboratory for evaluating new sorbent chemistries and evaluating sampling properties, discs, so far,

have only been produced in a manufacturing setting. Consequently, sorbent selection and device optimization have been restricted by market-driven considerations. As a consequence, the main applications of disc technology are generally narrowly focused on the needs of large volume users more so than is the case for conventional short packed columns.

Disc Formats

Solid-phase extraction discs are available in different styles and sizes. Particle-loaded membranes (Empore™ discs) contain 8–12 µm sorbent particles homogeneously distributed in a web of short poly(tetrafluoroethylene) (PTFE) fibrils. These are formed into 0.5-mm thick discs with diameters from 4 to 96 mm. They are flexible and superficially resemble filter paper discs. They are used with some supporting structure such as a fritted glass filter or porous plastic support. The discs contain about 90% by weight of sorbent with the balance being the PTFE microfibrils. Some characteristic physical properties are indicated in Table 1. Particle-loaded membranes are also available in a syringe barrel format similar to conventional short packed column-sampling devices. In this case, the sorbent bed contains particles of a larger diameter, about 50 µm, in thicker discs, about 1.0 mm, sealed into the base of a 4 mm (1 mL), 7 mm (3 mL), 10 mm (6 mL) and 20 mm diameter (40 mL) open syringe barrel. These discs have an integral prefilter consisting of a graded density of poly(propylene)

Table 1 Rough guide to the physical properties of solid-phase extraction disc according to disc diameter

Property	4 mm	7 mm	10 mm	25 mm	47 mm	90 mm

^aSilica-based sorbents.

microfibrils on the top sampling surface. They are recommended as a replacement for short packed column-sampling devices as well as for processing small volumes of viscous biological fluids. Particle-embedded glass fibre discs (SPECTM discs) contain particles of a narrow size distribution, about 10–30- μ m diameter, woven into a glass fibre-supporting matrix. The smaller diameter discs are rigid and self-supporting but large-diameter discs require a supporting structure similar to the particle-loaded membranes. Particle-embedded glass fibre discs are also available with a depth filter region of 0.1–0.2 mm combined with a sorbent extraction region of 0.8–0.9-mm thickness. Laminar discs (SpeedisksTM) contain 10 μ m sorbent particles in a consolidated 0.5- or 1-mm thick bed (usually) retained by two glass-fibre filters held in place by screens and a retaining ring in a preassembled cartridge with a 50-mm diameter sampling area. This configuration is designed to provide high sample flow rates for extracting large volumes of water.

Solid-phase extraction discs are available as loose discs for use in filtration-style apparatus for large volume samples and in open syringe barrels and cartridges for extracting intermediate and small sample volumes. These forms are compatible with sample processing using suction, positive pressure, syringe filtration and centrifugation. Common sorbents include octadecylsiloxane- and octylsiloxane-bonded silica particles, styrene-divinylbenzene porous polymers, porous polymer and silica-based cation and anion exchangers, mixed mode sorbents, activated carbon and immobilized crown ether sorbents. Other sorbents could easily be produced in a disc format if a sufficient market to support their production could be identified. Solid-phase extraction discs have been used primarily for sample preparation prior to chromatographic analysis. The disc format supports other, if minor applications at present, such as *in situ* detection using radioactivity counting, phosphorescence, and matrix-induced laser desorption mass spectrometry, etc. SPECTM discs can be inserted directly into a hole in a glass fibre thin-layer sheet and developed in a conventional manner combining recovery and separation into a single step. This ap-

proach is commonly used for toxicological screening of biological fluids.

Advantages of Disc Technology

The change in format from a short packed column to a disc has some attendant advantages for solid-phase extraction. These can be briefly summarized as follows. The larger cross-sectional area of discs and decreased pressure drop compared to conventional column-like sampling devices results in shorter sample processing times and decreased plugging by suspended particle matter. This is important in environmental surveillance programmes, such as the analysis of surface waters for persistent or toxic substances, where large sample sizes are common to obtain adequate detection limits and samples are often burdened by suspended particle matter. The large surface area per unit bed mass of the discs facilitates passive sampling approaches to solid-phase extraction and related uses as an indirect monitor of bioconcentration (discussed later).

The use of smaller diameter sorbent particles and the greater stability of the sorbent bed results in improved kinetic performance and reduced channeling. This allows the use of a smaller bed mass for extraction and results in less variation between sampling devices. The reduced bed mass provides cleaner sample backgrounds and lower interferences by minimizing nonspecific matrix adsorption. Smaller bed masses allow miniaturization of sampling devices for convenient handling of small sample sizes together with smaller elution volumes for analyte recovery. They also facilitate novel sampling approaches such as in-vial elution and on-disc derivatization (discussed later).

Kinetic Characteristics

Forced-flow planar chromatography has been used to study the kinetic properties of octadecylsiloxane-bonded silica particle-loaded membranes and particle-embedded glass fibre discs (Table 2). The total porosity of the discs is about 0.50, comprised mainly of interparticle porosity (about 0.40) with a large

Table 2 Kinetic properties of octadecylsiloxane-bonded silica solid-phase extraction discs

Property	Particle-loaded membranes	Particle-embedded glass fibre discs
Total porosity	0.52–0.54	0.51
Interparticle porosity	0.37–0.48	0.47
Intraparticle porosity	0.06–0.15	0.04
Specific permeability (10^{-14} m^{-2})	2.2–2.5	8.4
Flow resistance parameter	1000–1250	900–1000
Apparent particle size (μm)	5.8–7.7	15.3
Nominal pore diameter (nm)	6	8
Minimum plate height (μm)	56	
Optimum mobile phase velocity (mm s^{-1})	0.13	
<i>Coefficients for Knox equation</i>		
A	3.75 (0.5–1.5 for columns)	
B	1.72 (1.0–4.0 for columns)	
C	1.54 (0.05–0.7 for columns)	

fraction of the particle pore volume inaccessible to the mobile phase. This is not unusual for porous silica sorbents with a high loading of bonded phase restricting access to the pore volume. It is also compatible with the desire for a high sorption capacity and is not necessarily an undesirable feature. The specific permeability and flow resistance parameter support the hypothesis that the disc structure is homogeneous and devoid of through pores (holes), an essential requirement for a thin sampling medium. The apparent particle size for the particle-loaded membranes, about $7 \mu\text{m}$, and particle-embedded glass fibre discs, about $15 \mu\text{m}$, are in reasonable agreement with the manufacturers' claims given the assumptions used in calculations for converting the pressure–flow relationships to particle size values. The particle-loaded membrane provides an optimum plate height of $56 \mu\text{m}$ at a linear velocity of 0.13 mm s^{-1} . A 0.5-mm disc of 47-mm diameter will provide between 4 and 9 theoretical plates over the flow rate range of $5\text{--}100 \text{ mL min}^{-1}$ with a maximum value at 13 mL min^{-1} . Compared to typical slurry-packed columns, the contribution of both flow anisotropy and resistance to mass transfer to the plate height are unusually large for the particle-loaded membranes, and while the bed may have an homogeneous structure, it does not have an ideal kinetic structure. Fortunately, large plate numbers are not required for efficient extraction.

Disc Selection

The parameters of interest in selecting a disc for a particular application are size, sorbent chemistry and sample capacity. Referring to Table 2, large-diameter discs are used for processing large sample volumes to improve sample throughput. Small-diameter discs are used for processing small sample volumes and to recover analytes in a small solvent volume to eliminate the need for solvent evaporation

prior to analysis. Small-diameter discs are frequently used in clinical, forensic and pharmaceutical analysis and large-diameter discs in environmental analysis. The same sorbents used for conventional solid-phase extraction are generally used for disc extraction, but since discs are used for a narrower range of applications at present, the number of frequently used sorbent types is smaller (Table 3). The majority of applications proposed to date involve sampling of aqueous solutions. Octadecylsiloxane-bonded silica, poly(styrene-divinylbenzene) and activated carbon sorbents are used for general reversed-phase sampling; porous polymer and silica-based cation and anion exchangers are used for isolating ionizable and ionic compounds; and chelating ligands for the selective isolation of metals (particularly precious metals and radionuclides). Discs with different sorbent chemistries can be stacked on top of each other and analytes recovered in a single elution or as groups after physically separating the discs. Stacked discs of the same or varied sorbent chemistry are useful for extracting complex samples containing compounds that differ significantly in polarity or ionization, for achieving larger breakthrough volumes, and as an approach for reducing interferences by the selective sorption of the matrix by one disc and the analytes by the other. Stacked discs of a reversed-phase and cation exchange type are a suitable alternative to mixed-mode sorbents for isolating drugs and their metabolites from biological fluids. Discs containing porous polymer sorbents have been proposed for air sampling, particularly as a replacement for poly(urethane) foams, but have not been widely adopted.

In recent years, disc-based solid-phase extraction has become a popular technique for sample cleanup in ion chromatography and capillary electrophoresis. The interfering ions, often at relatively high concentrations, can mask, broaden or change the migration time of the ions of interest. The Novo-CleanTM discs

Table 3 Sorbent selection for disc applications

<i>Sorbent</i>	<i>General applications</i>
Octadecylsiloxane- and octylsiloxane-bonded silica	Octadecylsiloxane-bonded sorbents are widely used for reversed-phase sampling by non-specific sorption (and are more widely used than octylsiloxane-bonded sorbents). There are many applications to the extraction of non-polar and moderately polar pesticides (all classes), herbicides, phthalate and adipate esters, polycyclic aromatic compounds, food additives, pharmaceutical compounds, hydrocarbons and grease, etc. from aqueous solution. A large number of approved methods for water analysis.
Poly(styrene-divinylbenzene)	Used for compounds poorly extracted by octadecylsiloxane-bonded silica sorbents because of high water solubility such as polar pesticides, herbicides, phenols and pharmaceutical compounds. Lightly sulfonated, acylated and hydroxymethylated polymers claimed to provide higher recovery of neutral polar compounds because of better surface compatibility with aqueous samples.
Activated carbon	Applications similar to poly(styrene-divinylbenzene) but less frequently used. Methods proposed for triazine herbicides, some polar pesticides and <i>N</i> -nitrosodialkylamines.
Mixed mode	Usually co-bonded octadecylsiloxane and benzenesulfonic acid groups (or sorbent mixtures) used predominantly in clinical toxicology and pharmaceutical analysis for the simultaneous isolation of drugs and their metabolites. A number of established methods for drugs of abuse (marijuana and cocaine metabolites, amphetamines, phencyclidine and opiates) in biological fluids.
Sulphonic acid and quaternary amine ion exchangers	Selective isolation of ionic and easily ionizable compounds. Many methods for acidic herbicides and pesticides in water and basic drugs in biological fluids. Porous polymer sorbents are stable over the whole pH range. Sulphonated cation exchange polymers in the hydrogen, silver or barium forms used for cleanup of samples analysed by ion chromatography and capillary electrophoresis.
Crown ethers	Silica or other support with tethered mixed oxygen–nitrogen donor cryptands used for the selective isolation of metals by molecular recognition mechanisms. Commonly used for the isolation of precious metals (Pd, Pt, Rh) and radionuclides (Cs, Sr, Pb) from high concentrations of other metals to determine environmental burden and for dating geochemistry samples. Other applications include the removal of base metal impurities (Bi, Sb, Fe, Pb, Bi, Cu, Hg) from refinery streams, plating baths, etc.

contain a sulfonic acid-functionalized resin in the hydrogen, silver or barium forms housed in a cartridge adapted for syringe filtration. The hydrogen form is used to remove hydroxide and carbonate ions from samples by neutralization. The silver form is used to remove excess halide ions from samples by formation of insoluble silver halide salts that precipitate in the disc matrix. **Figure 1** shows an example of the detection of nitrate, fluoride and phosphate in a hydrochloric acid digest of a paper coating by capillary electrophoresis. The barium form is used to remove sulfate through the formation of insoluble barium sulfate.

Sample Processing

A generic outline for processing aqueous samples using disc technology is presented in **Table 4**. This

can be rescaled for different disc and sample sizes using the data in Table 1. The sampling process begins with decontamination of the disc by rinsing with organic solvent to remove impurities followed by solvent conditioning to facilitate effective and reproducible sorption of the analytes. Before the sample is added to the disc the conditioning solvent is rinsed from the disc with water to avoid premature breakthrough of analytes. For large sample volumes, a small amount of organic solvent (1–5% v/v) is added to aqueous samples to maintain a constant sample velocity. This usually has little influence on the breakthrough volumes except for porous polymer sorbents with a low degree of crosslinking. The selective adsorption of organic solvent by the polymer changes the sorbent volume and selectivity, resulting in changes in the breakthrough volume of up to an order of magnitude when either methanol,

Figure 1 Separation of trace concentrations of nitrate (1), fluoride (2) and phosphate (3) anions (1–10 p.p.m.) from a hydrochloric acid digest of a paper coating without treatment (A) and after disc cleanup using a Novo-Clean IC-Ag disc (B) by capillary electrophoresis. (Reproduced with permission from Saari-Nordhaus R and Anderson JM (1995) Membrane-based solid-phase extraction as a sample clean-up technique for anion analysis by capillary electrophoresis. *Journal of Chromatography A* 706: 563–569. Copyright Elsevier Science.)

2-propanol, acetonitrile or tetrahydrofuran are used as sample processing solvents (Table 5). These results are not in any way artifactual and are adequately predicted by the solvation parameter model for the breakthrough volumes. A sample processing solvent is not usually required for small sample volumes. Viscous samples may be easier to handle if diluted with either water or an organic solvent to increase their sample-processing rate. Samples containing a significant amount of particulate matter should be either prefiltered, processed with a filter aid (cover the surface of the disc with 1 cm of 40- μ m glass beads), processed by using a combination of a disc with an integral depth filter, or processed after adjusting the pH to dissolve soluble particles. Weak acids and bases are extracted by ion exchange or by ion suppression reversed-phase sampling at a suitable pH.

Increasing the ionic strength of the sample (e.g. adding sodium chloride) may improve the extraction of neutral compounds in reversed-phase extractions. The drying stage is important because water retained by the disc (and the disc support structure) contaminates the elution solvent and may cause difficulty if the solvent is to be reduced in volume or the analytes analysed by gas chromatography. Water may also reduce the efficiency of the elution step, particularly for elution solvents only partially miscible with water. Discs are usually dried by suction, but other possibilities include freeze-drying or desiccation over a drying agent with or without vacuum. For silica-based sorbents, a masking agent such as triethylamine (1% v/v) is sometimes added to the eluting solvent to increase the recovery of basic compounds strongly retained by interaction with silanol groups. Supercritical fluid extraction with carbon dioxide has been used to recover analytes isolated by disc extraction from water. In this case, the discs were used for preconcentration and media exchange since supercritical fluid carbon dioxide provides a poor extraction medium for aqueous solutions.

Passive Sampling and Bioconcentration

Passive sampling involves the extraction of organic compounds by immersion of the sampling disc in aqueous samples as opposed to filtering samples through the extraction disc. This process is convenient but little explored. One reason is the slow equilibrium of the extraction process even for stirred solutions. The uptake of organic compounds in a stirred solution depends on the size of the disc, time and the degree of mixing. Uptake by the disc may never be complete in a reasonable time but greater than 80%

Table 4 Generic guide for sample processing using solid-phase extraction discs. In this example, a 47-mm disc and a 1-litre water sample are used for illustration

Decontamination	With disc installed in filtration apparatus (or cartridge) rinse with 10 mL of solvent (acetonitrile) by allowing the solvent to soak into the membrane for a few minutes and then remove by suction.
Condition	As above but using 10 mL of methanol. Before the last drop of methanol has been sucked through the disc, add 10 mL of deionized water. The disc should not be allowed to suck dry until after the sample has been processed. It may be necessary to break the vacuum for ease of manipulating solutions.
Sample	The sample containing 1% (v/v) methanol is passed through the disc with a suitable reservoir in place. Filter aid or a prefilter may be required for samples with a heavy burden of particulate matter. The sample is processed at a flow rate between about 50 and 100 mL min ⁻¹ using a vacuum of about 10–20 mmHg.
Drying	Bulk water is removed from the disc and sampling apparatus by sucking air through the disc under full vacuum for about 3 min. Volatile compounds may be lost.
Recovery	The analytes are recovered by passing two 5-mL volumes of acetonitrile through the disc. The first volume of acetonitrile is allowed to soak into the disc for a few minutes and then gently sucked through the disc. Without letting the disc run dry, the second volume of solvent is added to the disc and sucked through the disc. The disc is then allowed to suck dry.

Table 5 Breakthrough volumes (cm³) of some organic compounds on porous polymer particle-loaded membrane discs with 1% (v/v) organic solvent in water

Compound	Acetonitrile	Tetrahydrofuran	2-Propanol	Methanol
Anisole	575	300	1750	1300
Acetanilide	95	25	100	75

Heptan-1-ol	2700	300	2700	1000
Propyl propanoate	1400	200	1250	750

extraction of pesticides in an agitated 500 mL sample using a 47-mm diameter particle-loaded membrane in 24 h was reported. Octadecylsiloxane-bonded silica discs have been explored as surrogate models for bioconcentration. This process is referred to as 'biomimetic extraction' and is used to estimate the selective uptake of organic compounds by aquatic species. Biomimetic extraction results in the preferential concentration of the more hydrophobic compounds from water and is theorized to provide a more realistic approach to assessing environmental effects of soluble organic compounds than results obtained by total extraction techniques. Measurements are made using passive disc sampling under conditions that avoid sample depletion to emulate the sorption of organic compounds by aquatic species. This is a relatively new approach to toxicity assessment and requires further work to establish a satisfactory relationship between the sorption properties of the disc and those of target aquatic species.

In-Vial Elution and Derivatization

The in-vial elution method reduces the amount of organic solvent used for recovery and eliminates tedious sample-preparation steps compared to conventional methods. This technique is an equilibrium-based approach for the recovery of extracted analytes. After extraction, the dried disc is placed in an autosampler vial and covered with a few mL of solvent. Recovery depends on the selection of the solvent, temperature and equilibration time. An equilibration time of 4 h, or overnight, at room temperature is sufficient in many cases to provide acceptable recovery (> 90%) and method precision as well as being compatible with automated sample analysis in gas and liquid chromatography. Addition of a derivatizing reagent to the solvent used for desorption allows both steps to be performed simultaneously in the same vial without removal of the disc. The vial can be sealed and heated to enhance the rate of derivatization. Common reactions employed so far include trimethylsilylation and alkylation for gas chromatographic analysis but other reagents should be equally applicable. It was demonstrated that ion

exchange discs catalyse the rate of alkylation of acid herbicides, surfactants and pesticides using a solution of an alkyl iodide as the derivatizing reagent. An example is shown in Figure 2.

Preservation and Storage

Samples or their extracts frequently have to be stored between sampling and analysis. Compounds differ in their stability to various storage conditions. The degradation or loss of pesticides and other organic compounds stored in water is mainly due to hydrolysis, biodegradation, photolysis and evaporation. Solid-phase extraction discs provide a convenient storage medium for compounds recovered from natural waters. General results indicate that discs provide equivalent or greater stability to the storage of pesticides in water at 4°C containing inhibitors to reduce

Figure 2 Use of in-vial elution and derivatization for the determination of chlorinated acid herbicides in an extract from a spiked (< 10 µg L⁻¹ each) river water sample by gas chromatography. A 500-mL sample was processed through a 25-mm strong anion-exchange disc, the disc dried by suction, sealed in an autosampler vial with 1 mL of acetonitrile and 0.2 mL of methyl iodide and heated at 80°C for 1 h, and excess methyl iodide removed by evaporation. (Reproduced with permission from Field JA and Monohan K (1996) Chlorinated acid herbicides in water by strong anion-exchange disc extraction and in-vial elution and derivatization. *Journal of Chromatography A* 741: 85–90. Copyright Elsevier Science.)

biodegradation. One of the primary mechanisms of disc degradation was identified as hydrolysis resulting from contact with water remaining in the disc after drying by suction. Stability was increased by desiccation of the discs. Stability has to be judged on an individual compound basis but discs provide a more efficient and convenient medium for extract preservation. Their low weight and small size make them a useful medium for shipping.

Automation and Multi-Well Formats

The introduction of solid-phase extraction discs occurred at a time when the automation of common laboratory process was very much in vogue for improving the quality of laboratory information and to reduce operating costs. Most disc extraction processes can be automated. Series-coupled filtration devices are popular for parallel processing of environmental water samples. Disc sampling devices in cartridge format are compatible with the automated and robotic workstations in use for automated sample preparation using conventional packed column formats. Multi-well microtitre plates have been adapted to disc extraction by incorporating the disc in the bottom of the well and using automated liquid-handling systems for high throughput extractions. This is achieved by a combination of automated parallel processing and eluent collection without volume reduction in a matching multi-well plate compatible with standard autoinjection devices. This approach meets the high sample throughputs demanded of current applications in bioanalysis and combinatorial chemistry for drug discovery. Short precolumns containing several discs stacked in series or packed with a spiral of particle-loaded membrane have been used for online extraction combined with liquid chromatography for pesticide monitoring of drinking and surface water samples. This is not an area that extraction discs dominate, and although useful and successful, clear advantages over short packed columns have not been demonstrated.

Future Developments

Most developments in disc technology are recent enough that they are still to some extent regarded as novel rather than routine laboratory tools. They are expected to continue to replace conventional short packed columns in those applications where the disc format has specific advantages. In addition, disc technology has already defined new opportunities for expansion of solid-phase extraction in passive sampling, storage and preservation of extracts, field sampling, and as an indirect indicator of bioconcentration.

Since discs are not laboratory-made products, the variety of disc chemistries available is linked to the identification of a viable market for a commercial product. For the present, this has tended to decouple efforts to promote disc technology from modern research on sorbent chemistry for the next generation of solid-phase extraction products.

SOLID-PHASE MATRIX DISPERSION: EXTRACTION

S. A. Barker, Louisiana State University,
Baton Rouge, LA, USA

Introduction

Matrix solid-phase dispersion (MSPD) is a patented analytical process for the preparation, extraction and fractionation of solid and/or viscous biological samples prior to instrumental or other forms of analysis. MSPD involves the direct mechanical blending of samples with standard solid-phase extraction (SPE) bonded-phase solid support materials. In this process, the bonded-phase support acts as both an abrasive to produce disruption of sample architecture and as a 'bound' solvent that assists in accomplishing sample disruption. The sample is dispersed over the surface of the bonded-phase support material, producing a unique mixed-character phase for conducting target analyte isolation. This process has been applied to the isolation of a wide range of drugs, pollutants and other compound classes from a variety of sample matrices. The factors affecting the use of MSPD and its applications for sample preparation, extraction and fractionation are addressed.

Development of MSPD

The classical application of all forms of liquid chromatography requires that the sample be applied in a liquid state to the head of the column. Thus, in order to accommodate the use of solid-phase extraction (SPE) columns and discs in the development of an analytical procedure, methodology must also be

developed to render the sample and target analytes contained therein into a liquid, relatively non-viscous, particulate-free and homogeneous condition. While some biological fluids are readily obtained in this form, most biological samples do not start out being directly applicable to SPE. This presents the analyst with some rather unique opportunities to apply or develop the best process for rendering a sample into a form compatible with liquid chromatography. Indeed, the most difficult and complex samples to analyse are the solids and semi-solids that are derived from a biological origin. Such samples may be obtained from animal or vegetable material and consist of a non-homogeneous array of fat and/or other tissues, fibre, pulp, etc.

For these and other reasons, the preparation of biological samples for SPE requires an initial disruption of the gross architecture of the sample. This step in the process assures access to all of the components of a sample and initiates the necessary homogeneity required for analysis. Disruption and homogenization also provide a larger overall surface area, generating greater access to solvents and reagents used for analyte isolation, which is the next step in the process. Samples that are by their nature already reasonably homogeneous, such as milk, fruit juices, plasma, etc., are less complicated in this regard but may be too viscous or contain particulates that could hinder rapid SPE extraction and fractionation. For such samples, dilution, filtration and/or centrifugation often solve these problems.

Classical processes for solid or semi-solid sample disruption usually involve one or various combinations

of the following: mincing, shredding, grinding, pulverizing and/or pressurizing of the sample. All of these approaches accomplish the basic requirement of disrupting sample architecture. This initial disruption may be followed or accompanied by the addition of solvents, acids, bases, buffers, abrasives, salts, detergents, chelators, etc., in an effort to more completely disrupt cellular and architectural composition and initiate the extraction and fractionation of various sample components from the analyte(s) of choice. Unfortunately, the creation of often intractable emulsions is often a consequence of these actions and repeated centrifugation, re-extraction and sample manipulation may be required to render the sample suitable for application to an SPE column. Application of this entire process strives to obtain the analyte(s) in solution, free from solids, emulsions or suspensions, reducing the solid sample to a homogenous liquid extract.

In 1989, a technique that remedied many of the complications of dealing with solid samples in their subsequent extraction using solid-phase materials was developed. This was accomplished by literally combining the sample directly with the bonded-phase solid support. This process, designated as matrix solid-phase dispersion (MSPD), was observed to simultaneously accomplish several steps in the more classical approach to sample preparation and SPE extraction/fractionation. A sample (tissue, fruit, etc.) is placed in a glass mortar containing a bonded-phase solid support material, such as octadecylsilyl silica (C_{18}). The solid support and sample are manually blended together using a glass pestle. In this process, the irregularly shaped silica-based solid support serves as an abrasive that promotes disruption of the sample's general architecture, and also acts as a bound solvent which appears to further disrupt the sample by inducing lysis of cell membranes. The blended material is packed into a column suitable for conducting sequential elution with solvents and the blended sample components, and their distribution in the bonded-phase support provides a new phase that exhibits a unique character for performing sample fractionation (Figure 1).

Examination of blended tissues by scanning electron microscopy (SEM) showed that sample architecture had been completely disrupted and that sample matrix components had apparently been evenly distributed over the surface of the bonded phase/support, forming an observable layer. The thickness of this 'new phase' of dispersed matrix is approximately 100 μm , similar to that of some micelle or membrane bilayers. Indeed, it appears that this is what occurs in the MSPD process. The sample is distributed over the surface of the bonded phase as a function of interac-

tions with the support and the bonded phase. The tissue matrix components themselves, form a layered phase consisting of support/lipophilic bonded-phase/sample lipids and a further distribution of sample-associated compounds arranged in and on this new phase based on their own relative polarities.

MSPD Versus Other Forms of Chromatography

MSPD is physically and functionally different from classical SPE in the following ways: (1) MSPD is a process that accomplishes sample disruption and dispersal onto particles of very small size, providing an enhanced surface area for subsequent extraction, whereas sample disruption must be conducted as a separate step in preparing samples for SPE; (2) SPE samples must be in a liquid form, relatively free of solids and of moderate viscosity before addition to the column, while MSPD directly handles solid or viscous liquid samples; and (3) The physical and chemical interactions of the components of the system are greater in MSPD and different, in some respects, from those seen in classical SPE or other forms of liquid chromatography.

In applying the MSPD process to a sample, the interactions observed between the individual components and the target analyte(s) involve (1) the sample components with the solid support, (2) the sample components with the bonded phase, (3) the analyte with the solid support, (4) the analyte with the bonded phase, (5) the analyte with the dispersed sample components, (6) all of the above interacting with the elution solvent(s) and their sequence of addition, and (7) the dynamic interactions of all of the above occurring simultaneously. Nonetheless, general chemical principles involved in conducting SPE and other forms of chromatography are also operable in applying MSPD. Thus, the chemical composition and characteristics of the solid support and bonded-phase are expected to affect the retention and elution of the analytes. These same properties will also apply to the dispersed sample components and the unique phase that is created.

Factors Affecting MSPD Extraction and Fractionation of Samples

To date, only the use of silica-based support materials has been reported for MSPD. The use and effect of synthetic polymer-based solid supports is a subject for further study, particularly supports that possess unique surface and pore chemistries, such as

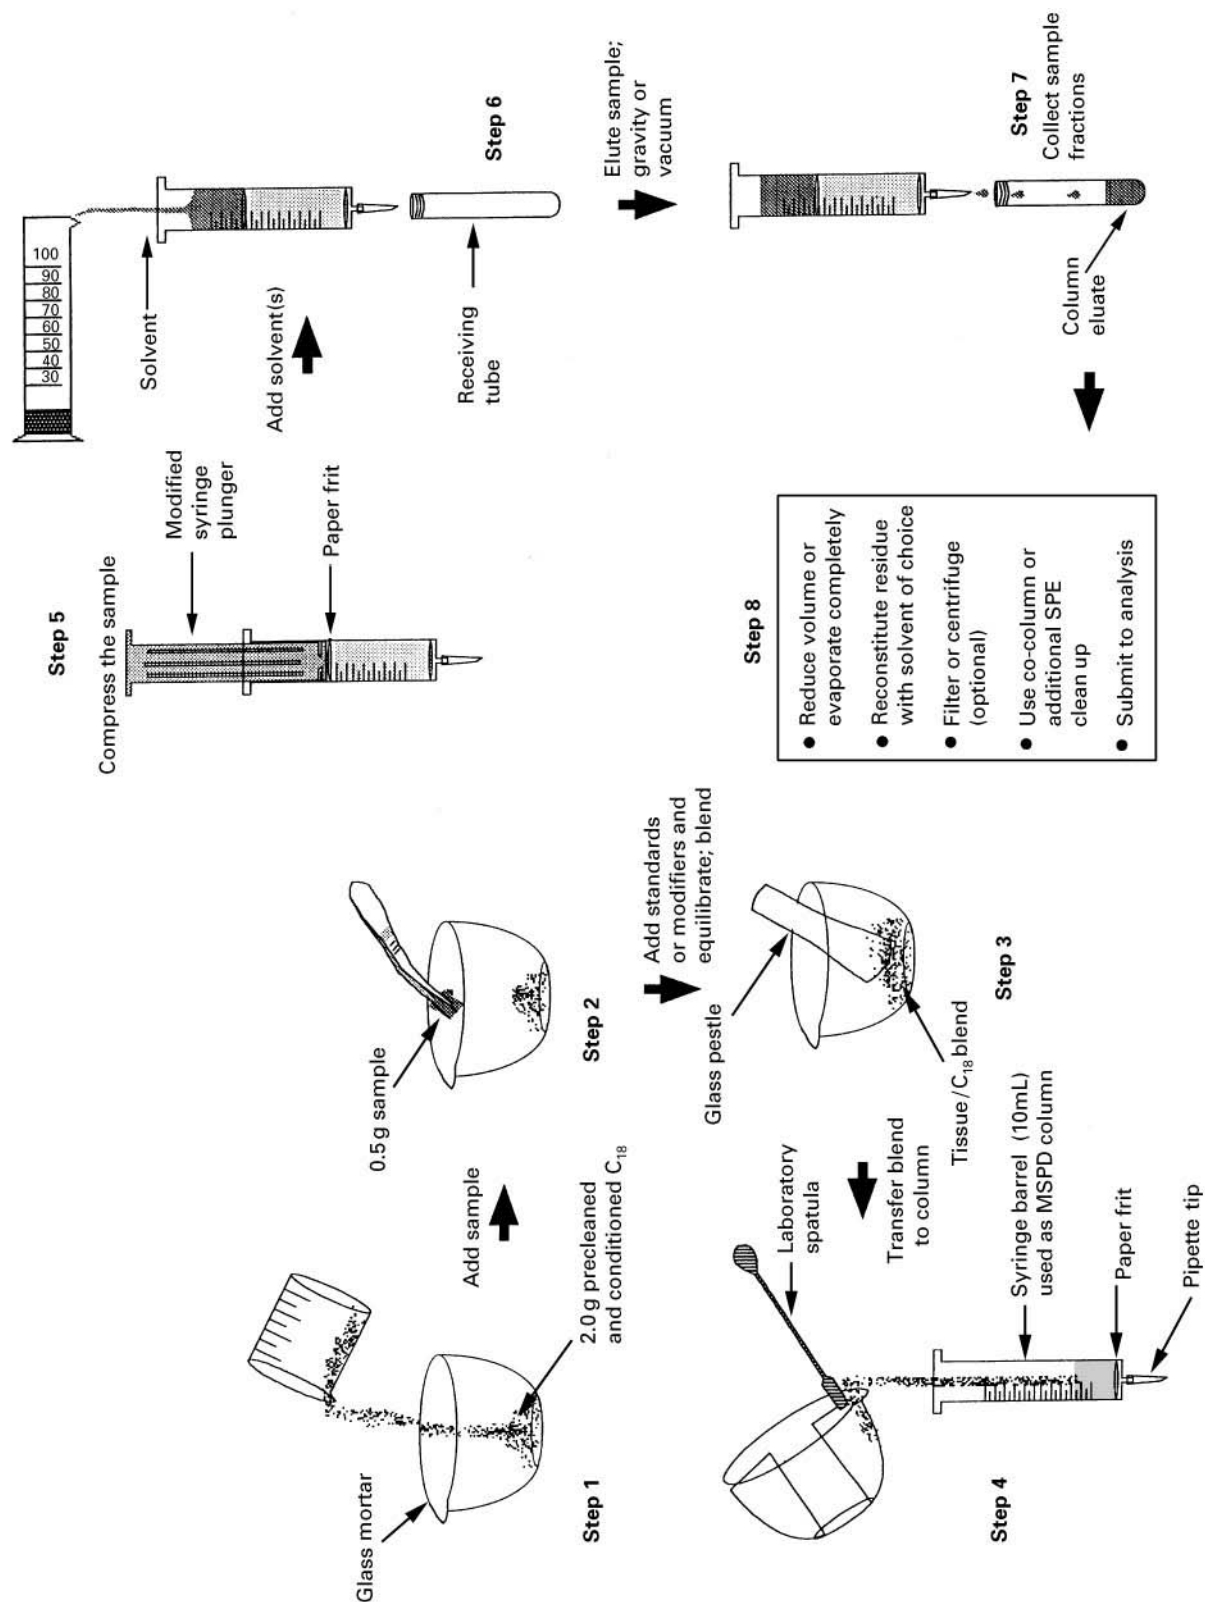

Figure 1 A schematic representation of a MSPD procedure.

hydrophobic interaction supports. For silica-based materials, however, studies have shown that the pore size is of minor importance in MSPD. This effect could vary with the sample and should be considered, however.

The effect of average particle-size diameter has also been examined. As may well be expected, the use of very small particle sizes (3–10 μm) leads to extended solvent elution times for a MSPD column, requiring excessive pressures to obtain adequate flow. However, 40- μm particle size materials (60 Å average pore diameter) have been used most frequently and quite successfully. It has been reported that a blend of silicas possessing a range of particle sizes (40–100 μm) also work quite well, and such materials also tend to be less expensive.

Depending on the application, non-encapped materials or materials having a range of carbon loading (8–18%) may also be used. It is a simple matter to examine these variables for a given application and should be considered for obtaining the best extraction efficiency and the cleanest sample.

The bonded phase will, of course, play a pivotal role. Depending on the polarity of the phase chosen, rather dramatic effects on the results may be observed and a range of available phases should be examined for each application. It has been reported that in applications requiring a lipophilic bonded phase, C_{18} and C_8 can be used interchangeably and that the best ratio of sample to bonded-phase material is 1 to 4. Most applications have employed lipophilic bonded-phase (C_{18}) materials, blending 2.0 g of solid support with 0.5 g of sample. The best ratio is, of course, dependent on the application and should be examined as a variable during method development. Ratios of bonded-phase to sample less than 4 : 1 have been used successfully and samples have been scaled up to 2 g from the typical 0.5 g used in most MSPD procedures, blended with a proportionately greater amount of solid support.

In general, it has been observed that the isolation of more polar analytes from biological samples is assisted by the use of polar phases (cyanopropyl, for example) and less polar analytes by less polar phases. This would be expected based on retention characteristics of compounds from classical SPE.

Preconditioning of the materials used for MSPD greatly enhances analyte recovery, as has been established with SPE. However, in MSPD it also appears to speed the process of sample blending and dispersal by breaking the surface tension differences that may exist between the sample and bonded-phase solid support. As with SPE, washing or rinsing the solid support materials prior to use also eliminates contaminants from the final eluates obtained for analysis.

MSPD column character may also be altered by modifying the matrix prior to or during the blending step. Several extraction studies designed to isolate a variety of different drugs have shown that addition of chelating agents, acids, bases, etc. at the time of blending affects the distribution and elution of target analytes from the sample. The elution profile of matrix components is likewise affected. This effect can be predicted from basic chemistry and applied in MSPD during sample blending and/or by alteration of the elution solvent composition. This effort to increase or suppress ionization of analytes and sample components greatly affects interactions of specific analytes with the blended phase and the eluting solvent(s). Thus, the use of matrix modification should be considered, as in SPE, as a possible variable to be controlled for attaining reproducible and efficient MSPD extraction.

The correct choice of elution solvents and the sequence of their application to a column is of utmost importance to the success of MSPD or SPE fractionation of samples. Elution solvent sequence and composition can be varied to obtain the best analytical results, when attempting to isolate the analyte or further clean the column of interfering substances with each solvent step. The nature of MSPD columns and the enhanced degree of interaction permit isolation of different polarity analytes or entire chemical classes of compounds in a single solvent or in differing polarity solvents passed through the column. This characteristic makes MSPD amenable to conducting multiresidue isolation and analysis on a single sample. In this regard, true gradient elution of a MSPD column has not been reported to date but should, nonetheless, prove applicable to the complete fractionation of samples.

It has been observed that, in an 8-mL elution of a 2-g C_{18} column blended with 0.5 g of sample, most of the target analytes eluted in the first 4 mL, or in approximately one column volume. This will, of course, vary with each application and with appropriate solvent selection but should be examined to reduce the use of solvent and the elution of other potentially interfering components.

The solid support, bonded phase and solvent elution sequence are all critical in performing MSPD, as they are in SPE. However, they may prove less influential overall than the effect of the sample matrix itself. It should be kept in mind that in MSPD the sample itself is dispersed throughout the column. In contrast, much of the sample is retained only in the first few millimeters of the column bed in SPE. In MSPD, the sample matrix components cover much of the bonded-phase support surface, creating a new phase that is dependent on their interactions with the

solid support and bonded phase, interactions that give the MSPD column its character. This new phase, in association with the analyte's distribution and own interactions with it, are perhaps the most important controlling factors.

This matrix effect has been seen by anyone who conducts chromatography, particularly on large numbers of samples that are less than pristine. Repeated sample injection can create a build-up of non-volatilized or non-eluting sample components at the head of a gas chromatography (GC) or liquid chromatography (LC) column, introducing a new 'phase'. This new phase may subsequently affect the stability, elution and retention character of target analytes as they come into contact with it. The discontinuity of phases within the analytical column may lead to peak tailing, the formation of shoulders or multiple peaks for a single analyte. It can lead, over time, to complete loss of analytes that interact strongly with the new phase. This 'matrix effect', or deposition of sample components as an additional phase, is incorporated throughout the column in MSPD. The dispersion of components establishes a new level of, and consistency in, equilibrium distribution of analytes that is fundamentally different from that seen from limited or discontinuous phases.

Another interesting aspect of this effect is that the analytes tend to co-elute in fractions that are not wholly consistent with predicted solubility behaviour. This observation may underscore a further unique property of MSPD. Elution of a sample is designed to remove the target analyte(s) but, even in SPE, one simultaneously fractionates and co-elutes some of the sample components. In MSPD the total amount of sample components present is much greater. In performing mass-balance experiments, it has been observed that the entire sample, minus a few per cent of what appeared to be denatured macromolecules and connective tissues, can be eluted from an MSPD column. Thus, sequential elution of liver tissue blended with C₁₈ recovers 98% of sample triglycerides in hexane and 98% of phospholipids and steroids in dichloromethane. Sugars and polyols are found in the acetonitrile fraction and phosphorylated sugars in water. The presence and concentration of eluted proteins follows the sequence methanol > water > acetonitrile > ethyl acetate. Approximately 7% of the total mass of the sample remains on the column, consisting of connective tissues and denatured macromolecules, including DNA and related nucleotide polymers. Thus, the MSPD process has been used to disrupt otherwise rugged and difficult-to-lyse bacteria, and to simultaneously perform fractionation of the sample for subsequent analysis to identify unique cellular components. These results

point to the fact that many of the unique elution properties of MSPD are due, not only to interactions of target analytes with the dispersed matrix but, also, an association of the matrix with the target analyte as specific classes of matrix components are eluted. Therefore, co-elution of target analyte in association with a particular class of matrix component, which is simultaneously interacting with the other materials remaining on the column, seems to be an important factor in the overall chromatographic character of the MSPD process.

The eluates obtained from an MSPD column are often amenable to immediate instrumental analysis, being adequately clean for direct injection. This is, of course, dependent on the sensitivity of the method and whether concentration is required before the analysis. However, in the majority of cases additional steps are required to address the removal of the co-eluting matrix components described above. In a number of cases this additional clean up of the sample has been accomplished by the use of secondary solid-phase materials. For example, bonded-phase material of the same polarity or even of different character than that used in blending can be packed at the bottom of the MSPD column (co-column). Alternatively, the MSPD column may be eluted directly onto a standard SPE column or disc material for the purposes of conducting further sample clean up and/or analyte concentration. Similarly, the eluate may be evaporated and reconstituted for application to another form of chromatography, analysis by immunoassay, etc. Other techniques employed to conduct MSPD eluate clean up have involved the use of classical liquid-liquid extraction, conducted on a small scale, prior to analysis.

While the process of preparing a MSPD column is currently a manual one, the steps of elution, collection and concentration of fractions, etc. are amenable to automation.

Conclusions

A list of MSPD applications for the isolation of a range of compounds from a variety of matrices is shown in Table 1. This list illustrates the rather generic character of MSPD for performing the extraction of a variety of matrices for a number of compounds. In most cases, MSPD has been found to provide equivalent results to older official methods conducted by more classical countercurrent and/or SPE techniques. Further, it has been rather consistently observed that MSPD requires 95% less solvent and can be performed in 90% of the time of such classical methods. The use of smaller sample sizes, combined with lower solvent consumption, purchase and disposal, make MSPD competitive

Table 1 Applications of MSPD to the analysis of residues in various matrices

with such methods on several levels and should be considered as an alternative when pursuing new analytical methodology. This is especially the case for solid or semi-solid biological materials.

Analysis of drugs in biological samples is growing in importance owing to the need to understand the therapeutic and toxic effects of drugs and to continue the development of more selective and effective drugs. Furthermore, the screening and confirmation of abused drugs in body fluids is important for the detection of potential users of drugs and the control of drug addicts following withdrawal therapy. Simultaneous analysis of these drugs in biological samples

is required in many circumstances, such as clinical control for diagnosis and treatment of diseases, doping control, forensic analysis and toxicology. Although high efficiency instruments have been developed, most analytical instruments cannot handle the sample matrix directly. Therefore, sample preparation is very important to achieve a practical and reliable method for the analysis of complex matrices such as biological samples. In general, over 80% of analysis time is spent on sampling and sample preparation steps such as extraction, concentration and isolation of analytes. However, previous sample preparation techniques, such as liquid-liquid extraction and solid-phase extraction, have their problems. These techniques are generally time-consuming and require large volumes of samples and solvents. For example, a long sample preparation time limits the number of samples that can be analysed, and multi-step procedures are prone to loss of analytes. Furthermore, the use of a large amount of solvent influences trace analysis, and also causes environmental pollution and health concerns. Ideally, sample preparation techniques should be fast, easy to use, inexpensive and compatible with a range of analytical instruments.

Solid-phase microextraction (SPME), developed by Pawliszyn and co-workers in 1990, is a new sample preparation technique using a fused-silica fibre that is coated on the outside with an appropriate stationary phase. The analyte in the sample is directly extracted onto the fibre coating. The method saves preparation time, solvent purchase and disposal costs, and can improve the detection limits. It has been used routinely in combination with gas chromatography (GC) and GC/mass spectrometry (GC/MS), and successfully applied to a wide variety of compounds, especially for the extraction of volatile and semi-volatile organic pollutants from water samples. SPME was also introduced for direct coupling with high performance liquid chromatography (HPLC) and LC/MS in order to analyse weakly volatile or thermally labile compounds not amenable to GC or GC/MS. The SPME/HPLC interface, equipped with a special desorption chamber, is utilized for solvent desorption prior to HPLC analysis, instead of thermal desorption in the injection port of the GC. Moreover, a new SPME/HPLC system known as in-tube SPME, was recently developed using an open-tubular fused-silica capillary column as the SPME device in place of the SPME fibre. In-tube SPME is suitable for automation, and automated sample handling procedures not only shorten the total analysis time, but also usually provide better accuracy and precision relative to manual techniques.

In this article, we review SPME techniques coupled with various analytical instruments and the

applications of these techniques to drug analysis. The review consists of two main parts. In the first part, general aspects of SPME techniques are surveyed for fibre and in-tube SPME methods coupled with various instruments. In the second part, applications of the SPME methods in drug analysis are considered according to the drug type.

SPME Techniques Coupled with Various Analytical Instruments

Fibre SPME

The fibre SPME device consists of a fibre holder and fibre assembly with built-in fibre inside the needle. In fibre SPME, analytes are extracted directly from the sample onto a polymeric stationary phase coated on the fibre. When the fibre is inserted into the sample, the target analytes partition from the sample matrix into the stationary phase until equilibrium is reached. Two types of fibre SPME techniques can be used to extract analytes: headspace SPME and immersion SPME. In headspace SPME, the fibre is exposed in the headspace of gaseous, liquid or solid samples. In immersion SPME, the fibre is directly immersed in liquid samples. The fibre with concentrated analytes is then transferred to an instrument for desorption, followed by separation and quantification. Headspace and immersion SPME techniques can be used in combination with any GC, GC/MS, HPLC and LC/MS system. The process of the fibre SPME/GC method is shown in Figure 1.

In fibre SPME, the amount of analyte extracted onto the fibre depends on the polarity and thickness of the stationary phase coating on the fibre, extraction time, and the concentration of analyte in a sample. In general, volatile compounds require a thick polymer coat and a thin coat is effective for semi-volatile compounds. Extraction of analytes is also typically improved by agitation, addition of salt to the sample, changing the pH, and temperature. Although full equilibration is not necessary for accurate and precise analysis by SPME, consistent extraction time and other SPME parameters are essential. Furthermore, it is important to keep a consistent vial size and sample volume. In general, immersion SPME is more sensitive than headspace SPME for analytes predominantly present in the liquid. On the other hand, headspace SPME is suitable for the extraction of more volatile compounds. Extractions from biological samples by headspace SPME exhibit lower background than extractions obtained by immersion SPME. Because the headspace and immersion SPME techniques differ in kinetics, both approaches should be evaluated to optimize fibre SPME conditions for

Figure 1 Schematic illustration of headspace and immersion SPME/GC methods. (A) Headspace SPME; (B) direct immersion SPME.

analytes. Fibre SPME techniques in combination with GC or GC/MS are unsuitable for the extraction of less volatile or thermally labile compounds. Thus derivatization approaches are frequently used to extract polar compounds from biological samples. Four types of derivatization techniques in combination with SPME are implemented. Direct derivatization in the sample matrix is similar to well-established approaches used in solvent extraction. Analytes are extracted by SPME after derivatization in the vial. For in-coating derivatization with the fibre-doping method, simultaneous derivatization and extraction are directly performed in the fibre coating by a two-step process: (1) dope fibre with derivatization agent and (2) expose doped

fibre to sample for extraction. This technique can be used for polar volatile compounds. Another in-coating derivatization technique is performed by the following two-step process: (1) dope fibre to sample for extraction and (2) expose doped fibre in the headspace of derivatizing agent. For derivatization in the injection port, the analyte extracted by SPME is desorbed in a GC injection port and then derivatized with additional reagent.

The desorption of analyte from the fibre coating is performed by heating the fibre in the injection port of a GC or GC/MS, or by loading solvent into the desorption chamber of the SPME/HPLC interface. Efficient thermal desorption of an analyte in a GC

injection port is dependent on the injection depth, injector temperature, and exposure time. A narrow-bore GC injector insert is required to ensure high linear flow and the fibre needs to be exposed immediately after the needle is introduced into the insert. Needle exposure depth should be adjusted to place the fibre in the centre of the hot injector zone. Desorption time is determined by the injector temperature and the linear flow rate around the fibre. The HPLC interface, on the other hand, consists of a six-port injection valve and a special desorption chamber, and requires solvent desorption of the analyte prior to HPLC or LC/MS analysis. A typical SPME/HPLC interface is shown in Figure 2. The desorption chamber is placed in the position of the injection loop. After sample extraction, the fibre is inserted into the desorption chamber at the 'load' position under ambient pressure. When the injector is changed to the 'inject' position, mobile phase contacts the fibre, desorbs the analytes, and delivers them to the HPLC column for separation. Two desorption techniques can be used to remove the analytes from the fibre: dynamic desorption and static desorption. In dynamic desorption, the analytes can be removed by a moving stream of mobile phase. When the analytes

are more strongly adsorbed to the fibre, the fibre can be soaked in mobile phase or other strong solvent for a specified time by static desorption before injection onto the HPLC column. In each desorption technique, rapid and complete desorption of analytes using minimal solvent is important for optimizing the SPME/HPLC or SPME/LC/MS methods.

In-tube SPME

In-tube SPME using an open-tubular capillary column as the SPME device was developed for coupling with HPLC or LC/MS. It is suitable for automation, and can continuously perform extraction, desorption and injection using a standard autosampler. With the in-tube SPME technique, organic compounds in aqueous samples are directly extracted from the sample into the internally coated stationary phase of a capillary column, and then desorbed by introducing a moving stream of mobile phase or static desorption solvent when the analytes are more strongly absorbed to the capillary coating. A schematic diagram of the automated in-tube SPME/LC/MS system is shown in Figure 3. The capillaries selected have coatings similar to those of commercially available SPME fibres. The capillary column is placed between the

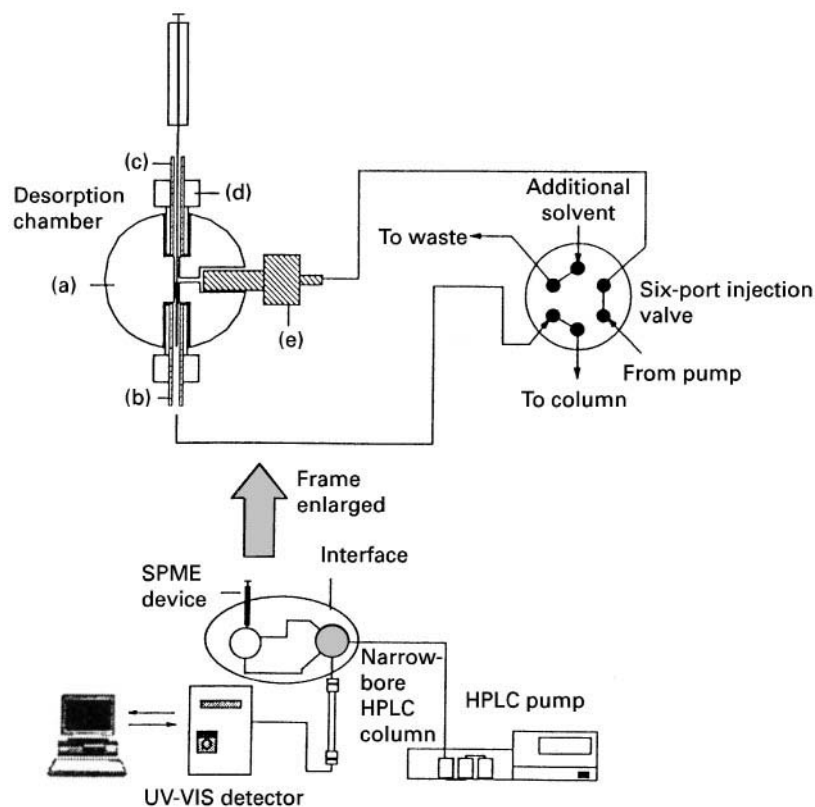

Figure 2 Schematic of the SPME-HPLC system. injection loop and the injection needle of the HPLC autosampler. While the injection syringe repeatedly draws and ejects sample from the vial under computer control, the analytes partition from the sample matrix into the stationary phase until equilibrium is reached. Subsequently, the extracted analytes are directly desorbed from the capillary coating by mobile phase flow or by aspirating a desorption solvent. The desorbed analytes are transported to the HPLC column for separation, and then detected with UV or a mass selective detector (MSD).

In in-tube SPME, the amount of analyte extracted by the stationary phase of the capillary column depends on the polarity of capillary coating, number and volume of draw/eject cycles and the sample pH. A capillary column 50–60 cm long is optimal for extraction. Below this level, extraction efficiency is reduced, and above this level, peak broadening is observed. In general, complete equilibrium extraction is not obtained for any of the analytes, because the analytes are partially desorbed into the mobile phase

during each eject step. The target analytes with higher K -values need longer equilibration times. Although an increase in number and volume of draw/eject cycles can enhance the extraction efficiency, peak broadening is often observed in this case. The optimal flow rate of draw/eject cycles is $50\text{--}100\ \mu\text{L min}^{-1}$. Below this level, extraction requires an inconveniently long time, and above this level, bubbles form on the inside of the capillary and extraction efficiency is reduced. The in-tube SPME technique does not need a special SPME/HPLC interface for desorption of analytes. The analytes extracted onto the capillary coating can be easily desorbed by a moving stream of mobile phase or desorption solvent when the analytes are more strongly adsorbed to the capillary coating. Carryover in the in-tube SPME method is lower or eliminated in comparison with the fibre-SPME method.

Although the theories of fibre and in-tube SPME methods are similar, the significant difference between these methods is that the extraction of analytes

is performed on the outer surface of the fibre for fibre-SPME and on the inner surface of the capillary column for in-tube SPME. Therefore, with the in-tube SPME method, it is necessary to prevent plugging of the capillary column and flow lines during extraction, and typically particles must be removed from samples by filtration before extraction. On the other hand, with the fibre-SPME method, it is not necessary to remove particles before extraction because they are removed by washing the fibre with water before insertion into the desorption chamber of the SPME/HPLC interface. Another significant difference between in-tube SPME and manual fibre-SPME/HPLC is the possible decoupling of desorption and injection with the in-tube SPME method. In the fibre-SPME method, analytes are desorbed during injection as the mobile phase passes over the fibre. On the other hand, in the in-tube SPME method, analytes are desorbed by mobile phase or by aspirating a desorption solvent from a second vial, and then transferred to the HPLC column by mobile-phase flow. The fibre-SPME/HPLC method also has the advantage of eliminating the solvent peak from the chromatogram, but peak broadening is sometimes observed because analytes can be slow to desorb from the fibre. With the in-tube SPME method, peak broadening is not observed because analytes are completely desorbed before injection.

Biomedical Applications: Drug Analysis

SPME methods applied to the analysis of various abused and therapeutic drugs in biological samples are listed in Table 1, according to the drug type, sample type, extraction device, extraction mode, and analytical technique. The SPME methods using 100- μm polydimethylsiloxane (PDMS) fibres in combination with GC or GC/MS are widely used for the analysis of various drugs. The SPME methods coupled with HPLC or LC/MS are used for the analysis of less volatile or thermally labile drugs. For recent reviews of some of these methods for drug analysis see Pawliszyn, Lord and Pawliszyn, Namera *et al.*, Junting *et al.*, Kataoka *et al.* and Sporkert and Pragst in the Further Reading section.

Amphetamines and Related Compounds

Yashiki and co-workers developed a simple and rapid method for analysing amphetamine (AM) and methamphetamine (MA) in urine and blood samples by headspace SPME and GC/MS-selected ion monitoring (SIM). In order to move the analytes into the headspace, the sample was heated at 80°C for 20 min under K_2CO_3 or NaOH alkaline conditions. Sub-

sequently, a 100- μm PDMS fibre was exposed to the headspace for 5 min, and then inserted into the injection port of GC/MS for desorption. The method was twenty times more sensitive than the conventional headspace method. Lord and Pawliszyn optimized several extraction parameters for the analysis of AM and MA in urine samples by headspace SPME/GC-flame ionization detection (FID). Centini *et al.* and Battu *et al.* reported simultaneous analysis of amphetamines and their analogues, such as 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxymethamphetamine (MDMA) and 3,4-methylenedioxyethylamphetamine (MDEA), in urine samples by headspace SPME using a 100- μm PDMS fibre. As shown in Figure 4, a clean total-ion chromatogram is obtained from a urine sample spiked with 100 ng mL⁻¹ of each of the 21 central nervous system stimulants and extracted by the headspace SPME method. Koide *et al.* applied this technique to the analysis of amphetamines in hair samples.

Degel, Penton, Ishii *et al.*, Makino *et al.* and Myung *et al.* used the direct immersion technique in order to improve the extraction efficiency and sensitivity. The extraction recoveries of AM and MA by the immersion SPME method are several times higher than those by the headspace SPME method. Ugland *et al.* reported an SPME technique in combination with derivatization. After derivatization with alkylchloroformate, amphetamines and their methylenedioxy analogues were analysed by immersion-fibre SPME/GC-nitrogen-phosphorus detection (NPD) or GC/MS.

Kataoka *et al.* developed an in-tube SPME/LC/MS method for the analysis of amphetamines and their methylenedioxy analogues using Omegawax (Supelco, Bellefonte, PA, USA) capillary as the extraction device. As shown in Figure 5, these drugs spiked into urine samples were selectively analysed without interference peaks by SIM-mode detection.

Anaesthetics

Kumazawa *et al.* developed headspace and direct-immersion-SPME methods for the analysis of ten local anaesthetics in blood samples. These drugs were extracted with 100- μm PDMS fibres after deproteinization of the sample with perchloric acid. Heating in a NaOH and $(\text{NH}_4)_2\text{SO}_4$ solution during headspace SPME gave the best recoveries of the drugs and the cleanest backgrounds. The recoveries for all drugs in the sample mixture at neutral pH in the presence of NaCl were greater than for that of a sample at the same pH without NaCl (see Figure 6). Although a small amount of background noise appeared in the direct immersion-SPME method, the advantage of using immersion-SPME is that recovery is much better than that of headspace-SPME.

^aHS: headspace; DI: direct immersion; IT: in-tube; D: derivatization.

Figure 4 Total-ion chromatogram of a urine sample extract spiked with 21 central nervous system stimulants at $1000 \mu\text{g L}^{-1}$. SPME conditions: fibre, $100 \mu\text{m}$ PDMS; extraction, at 80°C headspace for 10 min with stirring; desorption, exposure for 10 min in GC injection port. GC/MS conditions: column, PTA-5 ($30 \text{ m} \times 0.32 \text{ mm i.d.}$, $0.5 \mu\text{m}$ film thickness); injector, splitless mode at 200°C ; split opening time, 2 min; oven temperature, programme from 60 to 120°C at $30^\circ\text{C min}^{-1}$, then to 210°C at 5°C min^{-1} , and finally to 280°C at $30^\circ\text{C min}^{-1}$ and hold at 280°C for 5 min; transfer line and detector temperature, 280°C ; helium flow-rate, 1.3 mL min^{-1} ; ionization, 70 eV . (Reproduced with permission from Battu C, Marquet P, Fauconnet AL, Lacassie E and Lachâtre G (1998) *Journal of Chromatographic Science* 36: 1, by permission of Preston Publications, A Division of Preston Industries, Inc.)

Furthermore, Kumazawa *et al.* reported a method for analysis of phencyclidine in urine and whole blood by headspace-SPME and GC with a surface ionization detector (SID). Watanabe *et al.* developed a simple method for analysis of five local anaesthetics in blood samples by headspace SPME using a $100\text{-}\mu\text{m}$ PDMS fibre and GC/MS-SIM. Koster *et al.* reported direct immersion-SPME methods coupled with GC-FID and HPLC-UV for the determination of lidocaine in urine samples. Desorption of the PDMS fibre in HPLC is more complicated than the desorption in GC, because it is dependent on the composition of the mobile phase or the desorption solvent.

Antidepressants

Kumazawa *et al.* developed a simple headspace-SPME method for the analysis of four tricyclic antidepressants in urine and whole-blood samples. These drugs were extracted with a $100\text{-}\mu\text{m}$ PDMS fibre after heating at 100°C in the presence of a NaOH solution. Namera *et al.* reported a headspace-SPME/GC-MS method for the analysis of three tetracyclic antidepressants in whole-blood samples, and its application to a medicolegal case of setipitiline intoxication. Ulrich and Martens developed a direct immersion-SPME method for the simultaneous analysis of ten antidepressant drugs and metabolites in plasma sam-

ples, and applied the method to toxicological analysis after the accidental or suicidal intake of higher doses. The sample was extracted with a $100\text{-}\mu\text{m}$ PDMS fibre for 10 min and the fibre was exposed in the GC injection port at 260°C for 1 min after washing in 50% methanol and subsequent drying at room temperature. As shown in Figure 7, these drugs in plasma samples were selectively analysed by NPD without interference peaks. However, the recoveries of antidepressants from plasma samples were very low due to the high protein binding of these drugs. The limits of quantification for these drugs in plasma samples were $90\text{--}200 \text{ ng mL}^{-1}$. The sensitivity can be considerably improved by increasing the extraction time and dilution of plasma samples with water.

Benzodiazepines

Krogh *et al.* developed a direct immersion-SPME method in combination with GC-NPD for the analysis of diazepam in plasma samples. The polyacrylate (PA) fibre doped with 1-octanol was used to extract diazepam from the samples. The solvent-modified PA fibre was found to be more efficient in the extraction of diazepam than the untreated PA and PDMS fibres. This technique offers sufficient enrichment for bioanalysis, high selectivity, and short sample preparation time. However, the potential of the

Figure 5 Total ion and SIM chromatograms obtained from urine samples spiked with amphetamines by in-tube SPME/LC/MS. (A) Total ion chromatograms obtained from urine and spiked urine samples; (B) SIM chromatograms obtained from spiked urine sample. Urine sample ($10 \mu\text{L}$) was diluted ten times with water and used for analysis after filtration. Stimulants were spiked at a concentration of 5 mg mL^{-1} urine. LC/MS conditions: column, Supelcosil LC-CN ($3.3 \text{ cm} \times 4.6 \text{ mm i.d.}$, $3 \mu\text{m}$ particle size); column temperature, 25°C ; mobile phase, acetonitrile/ 50 mM ammonium acetate ($15:85$); flow-rate, 0.4 mL min^{-1} ; fragmentor voltage, 40 V ; ionization mode, positive ESI; SIM ion, $m/z = 136$ (AM), 150 (MA), 180 (MDA), 194 (MDMA) and 208 (MDEA). In-tube SPME conditions: capillary, Omegawax 250 ($60 \text{ cm} \times 0.25 \text{ mm i.d.}$, $0.25 \mu\text{m}$ film thickness); sample pH, 8.5 ; draw/eject cycles, 15 ; draw/eject volume, $35 \mu\text{L}$; draw/eject flow-rate, $100 \mu\text{L min}^{-1}$; desorption solvent, mobile phase. Peaks: 1, AM; 2, MDA; 3, MA; 4, MDMA; and 5, MDEA. (Reproduced with permission from Kataoka H, Lord HL and Pawliszyn J (2000) *Journal of Analytical Toxicology* 24: 263, by permission of Preston Publications, A Division of Preston Industries, Inc.)

solvent-modified SPME technique is limited by the incompatibility of the SPME coatings with most organic solvents. Luo *et al.* developed a direct immersion-SPME method for the simultaneous analysis of

five benzodiazepines in urine and serum samples. These drugs were efficiently extracted from these samples with a $65\text{-}\mu\text{m}$ Carbowax/divinylbenzene (DVB) fibre under conditions of saturated salt with

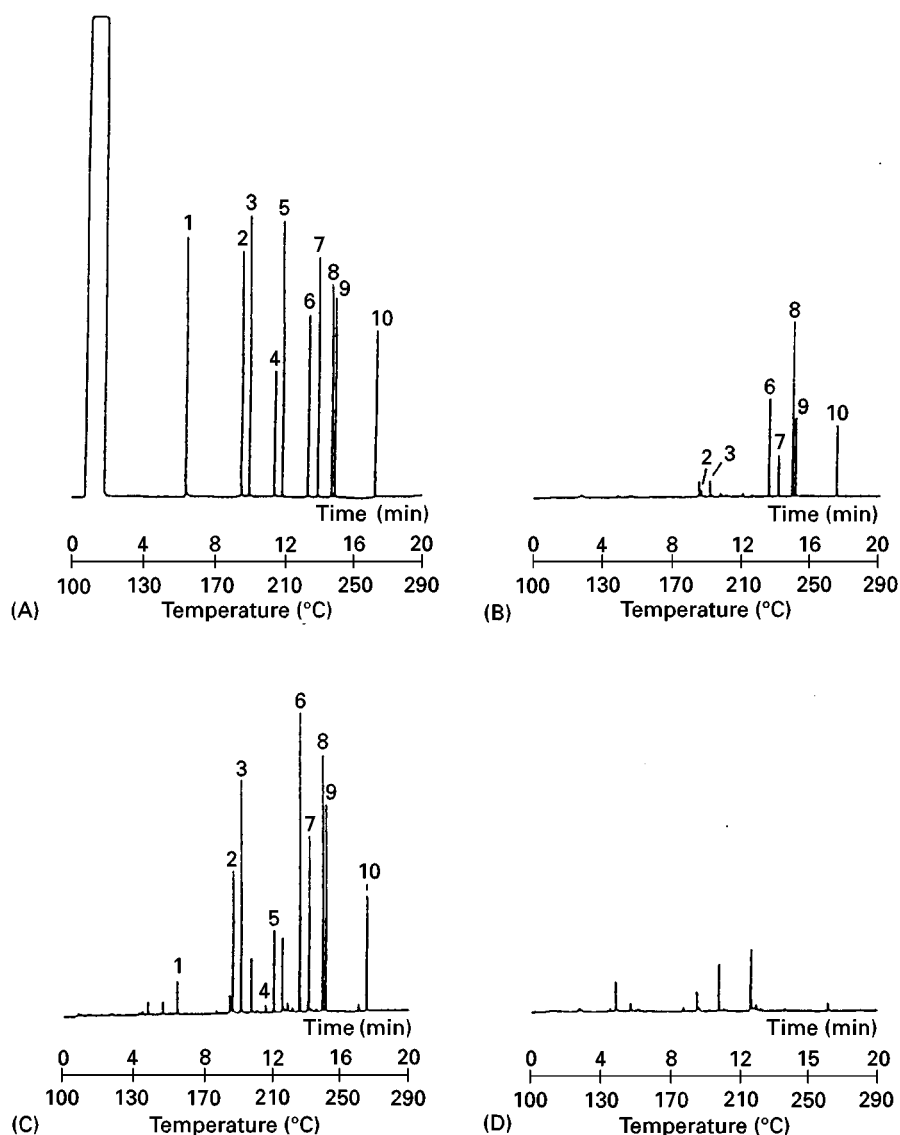

Figure 6 Capillary GC of ten local anaesthetics extracted from human whole blood by use of direct immersion-SPME. (A) The authentic drugs (50 ng each on column); (B) a drug extract at pH 7 without salt; (C) a drug extract at pH 7 in the presence of 0.5 g NaCl; (D) a blank extract at pH 7 in the presence of 0.5 g NaCl. The mixture of ten drugs (5 µg each) was added to 1 mL of human whole blood. SPME conditions: fibre, 100 µm PDMS; extraction, at room temperature for 40 min with stirring; desorption, 1 min exposure in GC injection port. GC conditions: column, DB-17 (30 m × 0.25 mm i.d., 0.25 µm film thickness); column temperature, initially hold at 100°C for 1 min and increase to 290°C at 10°C min⁻¹; injector and detector temperatures, 250°C; He carrier gas flow-rate, 3 mL min⁻¹; injection, splitless; detector, FID. Peaks: 1, ethyl aminobenzoate; 2, prilocaine; 3, lidocaine; 4, procaine; 5, mepivacaine; 6, tetracaine; 7, bupivacaine; 8, *p*-(butylamino)benzoic acid-2-(diethylamino)ethyl ester; 9, benoximate; and 10, dibucaine. (Reproduced with permission from Kumazawa T, Sato K, Seno H, Ishii A and Suzuki O (1996) *Chromatographia* 43: 59.)

pH 7 and sampling at 45°C with agitation, and analysed by GC-MS.

Guan *et al.* analysed the metabolites of benzodiazepines from acid-hydrolysed urine samples using a direct immersion-SPME method in combination with GC-electron capture detection (ECD). The detection limits were 2–20 ng mL⁻¹ for most drugs tested. Jinno and Taniguchi, however, developed an SPME method coupled with HPLC for the analysis of six benzodiazepines in human urine samples. Sensitiv-

ity may be increased by the combination of saturated salt and weakly alkaline conditions in the extraction matrix. As shown in Figure 8, a 65-µm PA fibre was found to be more efficient in the extraction of benzodiazepines than a 100-µm PDMS fibre.

Narcotics and Other Illicit Drugs

Kumazawa *et al.* and Makino *et al.* developed direct immersion SPME methods in combination with GC-NPD for the rapid analysis of cocaine in urine

Figure 7 Typical SPME-GLC-NPD chromatograms obtained from (A) blank plasma with internal standard, (B) plasma spiked with ten antidepressant drugs and metabolites, each 375 ng mL^{-1} , and (C) a sample of a patient after suicidal intoxication with amitriptyline (amitriptyline, 766 ng mL^{-1} ; nortriptyline, 489 ng mL^{-1}). SPME conditions: fibre, $100\text{-}\mu\text{m}$ PDMS; extraction, shaking at 700 rpm for 10 min at 22°C ; desorption, 1 min exposure in GC injection port. GC conditions: column, DB-1 ($30 \text{ m} \times 0.32 \text{ mm i.d.}$, $0.25 \text{ }\mu\text{m}$ film thickness); column temperature, programme from 140°C to 220°C at $20^\circ\text{C min}^{-1}$ and from 220°C to 270°C at 2°C min^{-1} ; injector and detector temperatures, 260°C and 300°C , respectively; N_2 carrier gas flow-rate, 0.7 mL min^{-1} ; injection, splitless; detector, NPD. Peaks: 1, amitriptyline; 2, trimipramine; 3, imipramine; 4a, *cis*-doxepine; 4b, *trans*-doxepine; 5, nortriptyline; 6, mianserine; 7, desipramine; 8, maprotiline; 9, clomipramine; and 10, desmethylclomipramine. IS, internal standard (chloramitriptyline). (Reproduced with permission from Ulrich S and Martens J (1997) *Journal of Chromatography B* 696: 217. Copyright Elsevier Science.)

Figure 8 Chromatograms of extracted drugs with (A) 100- μm PDMS and (B) 85- μm PA. SPME conditions: extraction, stirring at 840 rpm for 3 h at 60°C; desorption, 30 min exposure in desorption chamber. HPLC conditions: column, Siperiorex ODS (250 mm \times 1.5 mm i.d.); mobile phase, acetonitrile/water; flow-rate, 100 $\mu\text{L min}^{-1}$; detection, UV at 220 nm. Peaks: 1, nitrazepam; 2, flunitrazepam; 3, fludiazepam; 4, diazepam; 5, clotiazepam; and 6, medazepam. (Reproduced with permission from Jinno K and Taniguchi M (1997) *Chromatography* 18: 244.)

samples. Recovery of cocaine by this technique using a 100- μm PDMS fibre was 20%, and the detection limit was about 12 ng mL $^{-1}$. Lord and Pawliszyn applied the SPME/GC-FID method developed for amphetamines to the analysis of meperidine, codeine, methadone, morphine and heroin in spiked urine samples. Furthermore, Hall *et al.* applied an immersion SPME technique to the analysis of four cannabinoids in human saliva. These drugs were extracted with a 100- μm PDMS fibre and analysed in the range from 5 to 500 ng mL $^{-1}$ by GC/MS. Using this method, Δ^9 -tetrahydrocannabinol (Δ^9 -THA) was detected in a saliva sample collected 30 min after the subject had smoked marijuana (Figure 9).

Strano-Rossi and Chiarotti reported an immersion SPME method using a 30- μm PDMS fibre in combination with GC/MS for the analysis of cannabinoids in alkaline hydrolysed hair samples. The method is also applied to the analysis of other drugs such as methadone, cocaine and cocaethylene in hair samples.

Other Drugs

Yashiki *et al.* developed a simple and rapid method for the analysis of nicotine and its principal metabolite, cotinine, in urine samples using headspace SPME and GC/MS-SIM. Krogh *et al.* applied a direct immersion SPME technique to the analysis of the antiepileptic drug valproic acid in plasma samples. The drug was extracted with a 100- μm PDMS fibre after dialysis of plasma samples, and then analysed by GC-FID. Seno *et al.* developed headspace SPME methods for the simple analysis of five phenothiazine drugs and thirteen diphenylmethane antihistaminic drugs and their analogues in urine and whole blood samples. A 100- μm PDMS fibre was exposed in the headspace of the sample vial after preheating of the sample in the presence of NaOH, and the drugs extracted in the fibre were analysed by GC-FID. The recoveries from blood extracts were lower than those from urine extracts for all drugs. Hall and Brodbelt reported a direct immersion SPME method coupled with ion-trap GC/MS for the analysis of eight barbiturates in

Figure 9 Chromatograms after performing SPME on human saliva samples prior to and after marijuana smoking. (A) SIM chromatogram of saliva sample before marijuana smoking; (B) total ion chromatogram of saliva sample after marijuana smoking; (C) SIM chromatogram of saliva sample after marijuana smoking. SPME conditions: fibre, 100 μm PDMS; extraction, immersion for 10 min with stirring; desorption, exposure for 12 min in GC injection port. GC/MS conditions: column, DB-5ms (30 m \times 0.25 mm i.d., 0.5 μm film thickness); oven temperature, initially hold at 50°C for 0.2 min and increase to 280°C at 15°C min⁻¹, and finally hold at 280°C for 2 min; transfer line temperature, 280°C; detection, ion trap (electron ionization mode); SIM ion, Δ^9 -THC (m/z = 231, 299, 314). urine samples. A 65- μm Carbowax/DVB fibre was suitable for the extraction of these drugs. The detection limits reached 1 ng mL⁻¹. Okeyo *et al.* developed a straightforward method for performing derivatizing reactions of five steroids *in situ* in SPME fibres. After extraction of drugs from serum samples by direct immersion SPME, the drugs extracted on 85- μm PA fibre were derivatized in the headspace of the silylating reagent bis(trimethylsilyl)trifluoro-acetamide, and then analysed by GC/MS. With derivatization, SPME and GC analysis can be easily extended to the analysis of semi- and non-volatile compounds.

Volmer and Hui developed a SPME/LC/MS method for isolating and analysing eleven corticosteroids and two steroid conjugates from urine samples. After extraction in the vial by direct

immersion SPME using 65- μm Carbowax/DVB fibre, the drugs extracted in the fibre were desorbed in the desorption chamber of the SPME/HPLC interface, and then analysed by electrospray LC/MS. As shown in **Figure 10**, several corticosteroids and steroid sulfates spiked in urine samples were selectively analysed, although a minor peak was observed in the blank control urine in the SIM trace for cortisone.

Furthermore, Kataoka *et al.* developed an automated in-tube SPME/LC/MS method for the determination of the histamine H₂-receptor antagonist ranitidine in urine samples. The ranitidine in urine samples was directly extracted into Omegawax 250 capillary by 10 draw/eject cycles of 30 μL of sample at pH 8.5, desorbed from the capillary with

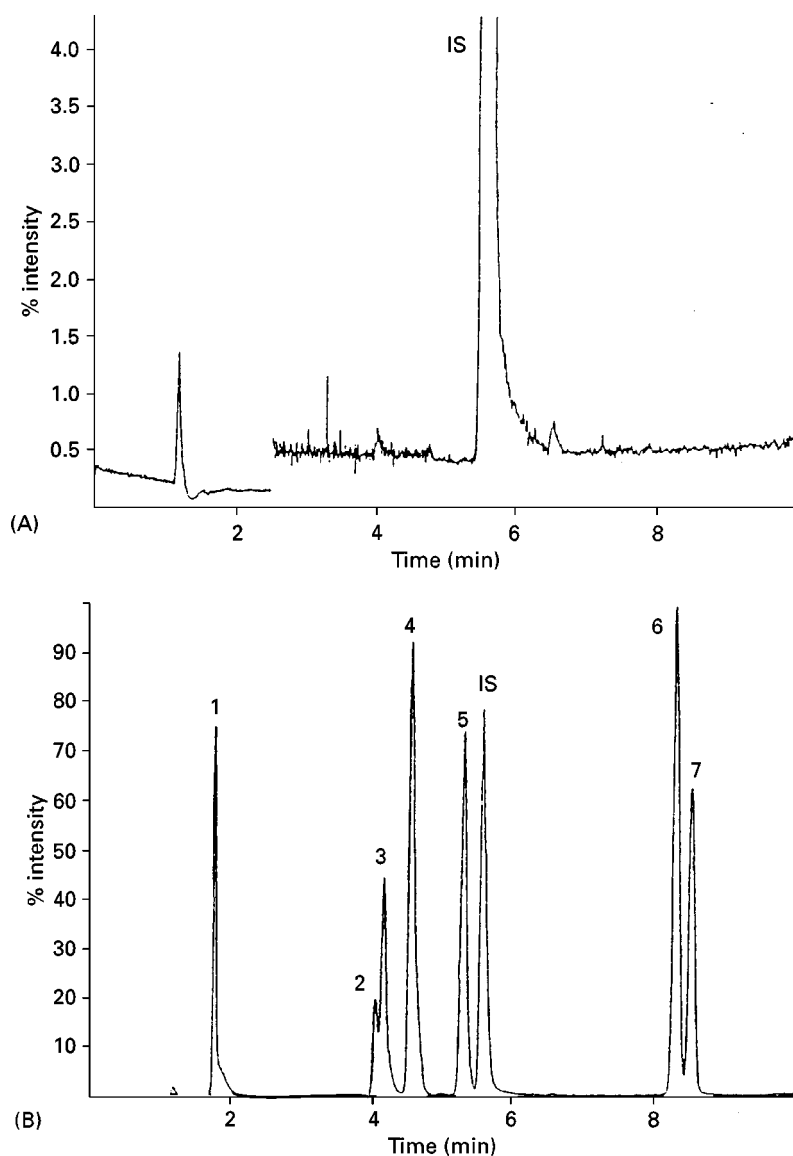

Figure 10 SPME/LC/MS analysis of several corticosteroids and steroid conjugates by time-scheduled SIM. The original urine sample was spiked at the 20 mg mL^{-1} level. (A) Blank control urine; (B) spiked urine. LC/MS conditions: column, YMC ODS-AQ ($50 \text{ mm} \times 4.0 \text{ mm i.d.}$, $3 \mu\text{m}$ particle size); column temperature, 25°C ; mobile phase, A = 100 mM ammonium acetate and B = acetonitrile/methanol ($50 : 50$; + 100 mM ammonium acetate), A : B was gradient programmed from $60 : 40$ to $20 : 80$ in 10 min ; flow-rate, 1 mL min^{-1} ; fragmentor voltage, 40 V ; ionization mode, negative ESI. SPME conditions: fibre, $65 \mu\text{m}$ carbowax/DVB; sample pH, 8.5 ; extraction, immersion for 15 min with stirring; desorption, methanol/water ($50 : 50$) for 5 min . Peaks: 1, estriol-3-sulfate; 2, cortisone; 3, fludrocortisone; 4, estrone-3-sulfate; 5, 6-methylprednisolone; 6, budesonide (epimer B); 7, budesonide (epimer A); IS = internal standard (niflumic acid) at $20 \mu\text{g mL}^{-1}$. methanol, and then analysed by electrospray LC/MS. Using this technique, nine beta-blockers and metabolites in urine and serum samples were also analysed. These methods were simple, rapid, selective and sensitive, and directly applied to urine samples and serum samples after ultrafiltration. Propranolol (PL) and its metabolites were successfully detected in the serum sample of a patient administered PL (see Figure 11).

Prospective of SPME in Biomedical Analysis

The main advantages of SPME are simplicity, rapidity, solvent elimination, high sensitivity, small sample volume, lower cost and simple automation. Since 1995, a number of SPME methods have been developed to extract drugs from various biological samples such as urine, serum, plasma, whole blood, saliva

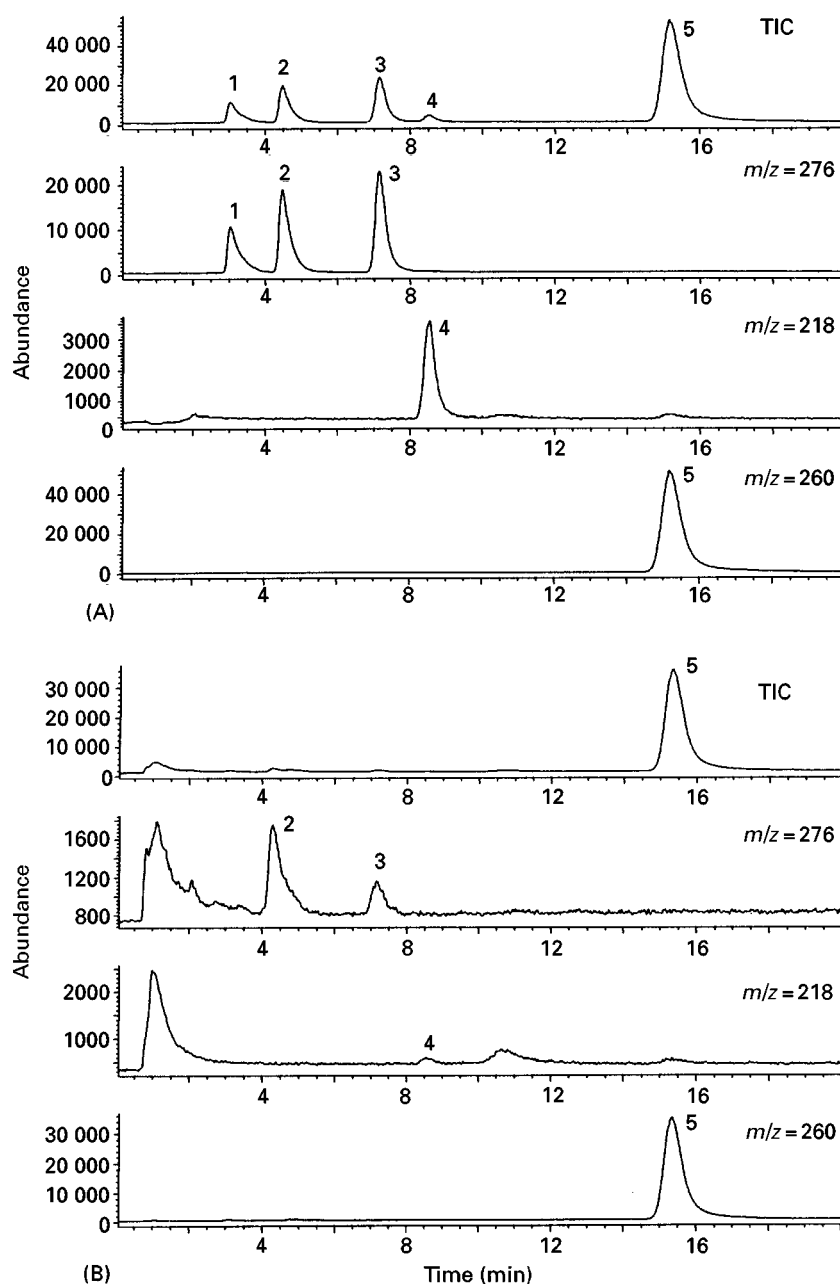

Figure 11 Total ion and SIM chromatograms obtained from standard propanolol and its metabolites, and a clinical serum sample by in-tube SPME/LC/MS. (A) Standard solution containing 200 ng mL^{-1} propanolol (PL), 50 ng mL^{-1} 4-hydroxypropanolol (4-OH-PL) and 7-hydroxypropanolol (7-OH-PL), 20 ng mL^{-1} 5-hydroxypropanolol (5-OH-PL) and *N*-desisopropylpropanolol (NDP). (B) Clinical serum sample ($100 \mu\text{L}$). Serum sample was diluted five times with 1% acetic acid and used for analysis after ultrafiltration. LC/MS conditions: column, Hypersil BDS C_{18} ($5.0 \text{ cm} \times 2.1 \text{ mm i.d.}$, $3 \mu\text{m}$ particle size); column temperature, 25°C ; mobile phase, acetonitrile/methanol/water/acetic acid (15 : 15 : 70 : 1); flow-rate, programme from 0.25 to 0.45 mL min^{-1} for 20 min run; fragmentor voltage, 70 V ; ionization mode, positive ESI; SIM ion, $m/z = 218$ (NDP), 276 (hydroxypropanolols) and 260 (PL). In-tube SPME conditions: capillary, Omegawax 250 ($60 \text{ cm} \times 0.25 \text{ mm i.d.}$, $0.25 \mu\text{m}$ film thickness); sample pH, 8.5; draw/eject cycles, 15; draw/eject volume, $35 \mu\text{L}$; draw/eject flow-rate, $100 \mu\text{L min}^{-1}$; desorption solvent, mobile phase. Peaks: 1, 5-OH-PL; 2, 4-OH-PL; 3, 7-OH-PL; 4, NDP; and 5, PL. (Reproduced with permission from Kataoka H, Narimatsu S, Lord HL and Pawliszyn J (1999) *Journal of Analytical Chemistry* 71: 4237. Copyright American Chemical Society.)

and hair. The affinity of the fibre coating for an analyte is the most important factor in SPME. As shown in Table 1, fibre coatings of different polarity and thickness were selected for each drug. Most drugs

in biological samples were extracted with $100\text{-}\mu\text{m}$ PDMS for nonpolar drugs and $85\text{-}\mu\text{m}$ PA for polar drugs. A solvent-modified fibre can improve selectivity and shorten extraction time. Although the theories

of fibre and in-tube SPME methods are similar, there are significant differences between these methods. The extraction of analytes is performed on the outer surface of the fibre for fibre SPME and in the inner surface of the capillary for in-tube SPME. Commercially available SPME fibres for drug analysis are limited, by GC capillary columns with a vast array of stationary phases are commercially available for in-tube SPME. Headspace fibre SPME is suitable for the extraction of drugs in gaseous, liquid and solid samples, because of the avoidance of contact with an aggressive matrix incompatible with the fibre. Direct immersion fibre SPME can be used to extract drugs from clear and cloudy liquid samples, however, in-tube SPME is limited to the extraction of clear liquid samples. The headspace SPME technique, therefore, is suitable for direct extraction from whole blood samples, while immersion fibre SPME or in-tube SPME methods require deproteinization or ultrafiltration of these samples prior to extraction. As mentioned above, the extraction efficiency of fibre SPME depends on extraction time, agitation, heating, sample pH and salt concentration. For in-tube SPME, number, volume and speed of draw/eject cycles, and sample pH are important factors for efficient extraction. On the other hand, the desorption of analyte from a fibre or capillary coating depends on the temperature of the injection port and exposure time in combination with GC or GC/MS, or component and volume of solvent when used in combination with HPLC or LC/MS. Therefore, these SPME parameters should be optimized when developing a new SPME method for drug analysis.

With further development of new coating materials, such as affinity coatings for target drugs and chiral coatings for optically active drugs, the further development of derivatization methods, further coupling with different analytical instruments, such as capillary electrophoresis, and improvement of the extraction and desorption conditions, the SPME technique is expected to be widely applied in the future for highly efficient extraction of drugs from various biological samples.

Introduction

Solid-phase microextraction (SPME) was first described by Pawliszyn and co-workers from the University of Waterloo in 1989 and has rapidly become a popular extraction method in research.

Briefly, SPME uses an immobilized liquid polymer phase coated on the outside of a fused silica fibre. By dipping this fibre into either a liquid (usually aqueous) sample, or the headspace above a liquid sample, absorption of the analytes from the matrix into the polymer layer occurs. Analyte desorption occurs in either the heated inlet port of a gas chromatograph or a specially constructed inlet loop in the case of liquid chromatographic analysis.

Adjustment of the sample pH or ionic strength can be used to enhance the analyte partitioning into the fibre coating. The adjustment of ionic strength is commonly carried out by the addition of an inorganic salt such as sodium chloride. To reduce the time taken for equilibrium between the fibre coating and the sample agitation is used. This is usually achieved with a magnetic stir bar system.

SPME has the advantage that it is a solvent-free technique, which reduces both environmental pollution and sample preparation time, as no additional concentration step is required. There is no packed cartridge bed, as with solid-phase extraction (SPE), and so SPME does not suffer from plugging and is complete in two stages. This minimizes the chance of analyte loss or operator error.

There are now many examples of the extraction of analytes of environmental interest. This article will cover the more recent examples from each class of environmental pollutants. Articles listed in the Further Reading cover these areas in more depth than is possible here.

Volatile Organic Chemicals

One of the most common environmental applications of SPME is the analysis of volatile organic compounds. The chemicals frequently used as representative of this class are benzene, toluene, ethylbenzene and the xylene isomers (BTEX).

Most BTEX extractions have been carried out using polydimethylsiloxane (PDMS) as the polymer

coating on the fibre. Whilst PDMS works well for the extraction of the BTEX compounds, the recoveries from the sample are typically in the 0.1–10% range. With such a low recovery, the limits of detection (LOD) are often higher than those achieved with conventional purge-and-trap analysis.

An interesting way to reduce LODs without resorting to more expensive detectors is to use a fibre freshly coated with PDMS that is then dipped in extra-fine powdered activated charcoal. The total thickness of this coating is approximately 100 μm , which is similar to the thickness of a commercially available fibre.

Using the PDMS/charcoal-coated fibre, recoveries of greater than 90% are achieved in about 15 min extraction time at 25°C, or in under 10 min at 75°C using headspace analysis and salting out of the sample, as illustrated in **Figure 1**. These high recoveries give LODs of $\leq 21 \text{ pg mL}^{-1}$ with GC analysis using a flame ionization detector (FID). This is over an order of magnitude better than the LODs for the US Environmental Protection Agency method 524.2, and two orders better than conventional PDMS SPME with gas chromatography (GC)-FID analysis.

Surfactants

Alkylphenol surfactants are becoming of increasing concern due to their possible role as endocrine disrupters. SPME analysis of this class of surfactants eliminates the need for the concentration step frequently required with conventional liquid–liquid extraction or SPE.

As alkylphenol ethoxylate surfactants are not amenable to GC analysis without derivatization, and SPME with derivatization is a much less well-developed technique than classical SPME, analysis of the surfactants has been accomplished by normal-phase gradient high performance liquid chromatography (HPLC) with UV detection.

This requires a specific interface for desorbing the surfactants from the fibre after adsorption (**Figure 2**). The fibre desorption chamber is a three-way tee in which two outlets are connected to the injection valve and the third houses the SPME device. Flow to the tee is via stainless steel tubing (d) and back to the injection port is via poly(ether ether ketone) (PEEK) tubing (e) connected via a finger-tight PEEK union (f). The SPME device (g) is positioned in the top part of the tee. One of the problems initially encountered with this device was stripping of the fibre coating by

Figure 1 Dependence of extraction efficiency on exposure time and temperature. BTEX concentration, 500 pg mL^{-1} of each compound; stirring speed, 50% of maximum; amount of NaCl, 15 g. the narrow internal diameter stainless steel tubing (d). This was because of swelling of the coating, which occurred in the desorption solvents used. Increasing the diameter of the tubing to account for this swelling solved this problem. In order to be able to withstand the high pressures used in HPLC, a slip-free supercritical fluid extraction connector (i) was used to provide a strong seal. A large diameter Teflon tube (h) and a regular ferrule (j) complete the desorption device.

When analysing for surfactants, it is important that the extraction method does not discriminate against any of the oligomers present in the sample. A Carbowax/template resin-coated SPME fibre was found to show good extraction of the various chain length surfactants. To ensure that the extracted ethoxamer

distribution was the same as the original sample, salting out of the sample was carried out; without this, a bias towards shorter chain ethoxamers is obtained.

The final analysis method has been successfully applied to the determination of a number of surfactants, as shown in Figure 3. LODs for the individual alkylphenol ethoxamers are in the low p.p.b. range.

Hetero-organic Pollutants

Compounds with nitrogen, sulfur or oxygen (NSO) in the aromatic ring system are frequently encountered as pollutants in groundwater. These hetero-organic pollutants are often the result of creosote contamination. For NSO groundwater analysis, LODs in the ng L^{-1} range are required. Currently this is only achievable with liquid-liquid extraction using a concentration step.

For SPME analysis of NSOs, out of three fibre coatings investigated, PDMS, polyacrylate (PA) and Carbowax, only the PA coating successfully extracted all of the 15 NSO compounds investigated. However, the amount extracted at equilibrium is small, ranging from 0.4% for pyrrole to 57% for dibenzofuran. Although pH over the range of 7–10 does not affect the amount extracted, higher pH values degrade the fibre coating. Adjusting the sample ionic strength by adding sodium chloride increases the amount extracted.

The LODs obtained, distribution coefficients and aqueous solubility of the NSO compounds investigated are shown in Table 1. In comparison to a conventional analysis this SPME method showed improved performance for water soluble and semivolatile NSOs, but poorer performance for the volatile NSOs. Carryover from one sample to the next was also a problem and necessitated a 10 min offline fibre cleaning process between samples. Fibres were found to degrade slowly with use, and were discarded after 50 analyses.

Pesticides and Herbicides

The monitoring of groundwater for pesticide and herbicide contamination is a common environmental analysis. Accordingly, there have been a number of reports on the use of SPME for pesticide extraction. Many different classes of pesticides have been studied, including the organochlorine and organophosphorus pesticides.

With organophosphorus pesticides, the best fibre coating is an XAD polymer (polystyrene-divinylbenzene)

Figure 2 Modified SPME-LC interface in (A) the fibre desorption and (B) insertion modes. Arrows indicate flow direction. Reproduced with permission from Boyd-Boland and Pawliszyn (1996). Copyright American Chemical Society.

phase. The aromatic character of this material provides superior extraction for many of the organophosphorus pesticides in comparison to a PDMS phase. This class of pesticides is one group of compounds where salting out has no beneficial effect. The limitation of the SPME extraction was that the

relative standard deviation (RSD) values seen were very large – up to 80% in some cases. In addition, some carryover from run to run was experienced. Until these problems can be solved, the method is more suitable for screening than for routine analysis.

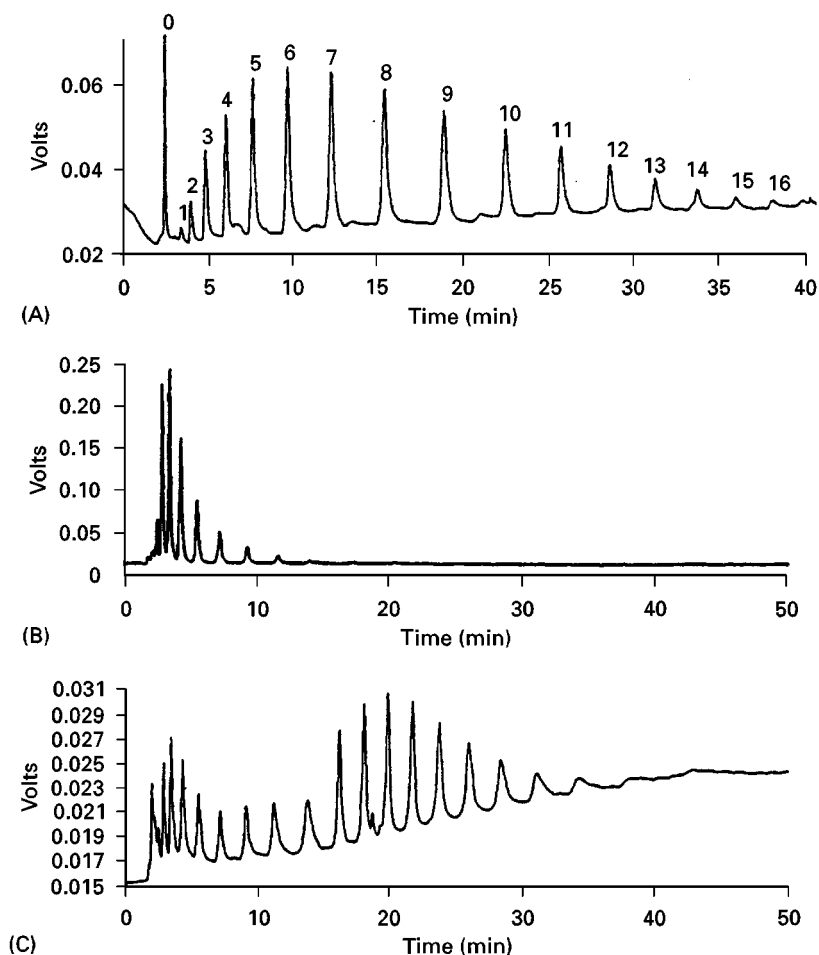

Figure 3 LC chromatograms of the extracted alkylphenol ethoxylates: (A) Triton X-100; (B) Rexol 25/4; (C) Rexol 25/5. Peak assignment in (A) refers to the number of units in the ethoxylate chain. Reproduced with permission from Boyd-Boland and Pawliszyn (1996). Copyright American Chemical Society.

One of the great areas of potential for SPME is automated analysis. This has been partially demonstrated in the field of pesticide analysis by coupling SPME extraction from a flow cell with GC-FID. The online flow-through cell used is shown in **Figure 4**. The extraction is performed whilst pumping the sample in a closed loop for 30 min. Changing the flow rate from 0.1 to 10 mL min⁻¹ did not affect the precision of the extraction, presumably because flow inside the extraction chamber where the fibre is positioned is turbulent across this entire range. Method precision was found to compare well with other sample agitation methods, such as fibre vibration or magnetic stirring.

This method has been applied to the analysis of the S-triazines (herbicides) and, although not fully automated, as operator intervention was required to transfer the SPME fibre from the extraction cell to the GC, it is clearly a step in that direction.

Polycyclic Aromatic Hydrocarbons and Polychlorinated Biphenyls

Many of the samples analysed for environmental contamination are solids, in particular soils and sludges. These present a challenge to SPME, particularly in the case of semivolatiles, such as polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), where heating and headspace extraction cannot be used.

A solution to this problem is first to extract the analytes of interest with subcritical water and then extract the resulting subcritical water solution via SPME. In this way, no hazardous solvents of any kind are used during the extraction procedure.

Extractions are carried out in a heavy-duty stainless steel pipe partially filled with solid sample and approximately 3.5 mL of HPLC-grade water. Care should be taken to avoid samples which might react with water leading to pressures higher than expected.

Table 1 The measured distribution constants between polyacrylate fibre and water, the octanol–water partition coefficients ($\log K_{ow}$), aqueous solubility (mg L^{-1}), limit of detection of NSO by SPME-GC-FID and SPME-GC-ITMS in $\mu\text{g L}^{-1}$ and %RSD

The sealed pipe is then heated in a GC oven for an initial extraction time period. After cooling, conventional SPME extraction using a $100 \mu\text{m}$ PDMS-coated fibre of 1.8 mL of the resulting supernatant liquid is carried out in a 2 mL vial.

Increasing the temperature of the water extraction to 250°C improved the extraction of PAHs but further increases in temperature did not improve the results. Increasing the water extraction time from 15 to 60 minutes also increased the amount of PAHs

**Figure 4** Instrumental set-up for the online flow-through cell. The SPME fibre hosts in a Valco-tee unit sealed by a vespel ferrule. Copyright Elsevier Science.

extracted, but not by enough to justify the increased time taken for the extraction procedure. One point of note was the unusual conversion of d_{10} -anthracene to d_8 -anthracene during the extraction. This was unexpected, as the hot liquid water used is regarded as being relatively unreactive and other deuterated standards did not show the same effect.

Partitioning of the higher molecular weight PAHs back on to the soil during cooling of the water extract was found to be a problem that affected quantification, unless deuterated standards for each compound were added.

PCBs are another ubiquitous environmental pollutant that have been determined by using SPME extraction in a variety of water samples. Conventional 100 μm PDMS fibres were found to give sufficient extraction of PCBs from water samples in 15 min to have a LOD of around 5 pg mL^{-1} for each congener with GC and electron-capture detection. This would allow reasonably fast screening of samples for the presence of PCBs.

Carryover was found to be present on not only the SPME fibres, but also the Teflon coated stir-bars, which were used to agitate the solution for more efficient extraction. New stir bars were required for each sample to avoid this problem. Eliminating fibre carryover was more difficult but offline desorption, coupled with running blanks between every sample, minimized the problem.

Old fibres (used more than 30 times) were found to show more severe carryover than new fibres. This

degradation in use meant that even with the off-line desorption, carryover could still be present, and would necessitate regular changing of the fibre.

In contrast to many other SPME studies, it was found that no direct correlation existed between the octanol-water partitioning coefficient (K_{ow}) and the fibre-water coefficient (K_{SPME}). The deviations begin to occur with analytes of molecular mass greater than 200 and, hence, for these compounds, K_{ow} cannot be used to estimate K_{SPME} .

Suspended solids in real water matrices were found to reduce the aqueous PCB concentration by up to 50% after spiking within 24 h. This partitioning on to suspended solids is similar to that seen for PAHs.

Chlorobenzenes

Chlorobenzenes are classified as priority pollutants in both the US and the European Union. SPME has been evaluated in both the headspace sampling and direct sampling modes for the determination of chlorobenzenes in soil samples. One of the problems of using SPME with soil samples is that quantification problems occur with soil samples that have a high organic content when using the external calibration method. This has necessitated the use of the standard addition method for reliable quantitation.

Another problem with heavily contaminated soils is the overloading of the detector beyond the linear dynamic range by the large amount of analyte extracted. This is a particular problem with detectors such

Figure 5 Effect of (A) (circles; 10%; triangles, 30%) methanol and (B) (circles, 20%; triangles, 30%) acetone on the absorption time profile of pentachlorobenzene by direct SPME-GC-ITMS using a 100 μm PDMS fibre with 0.030 g of soil, 40 mL of water-organic solvent; stirring speed 1000 rpm, sampling temperature 30°C, exposure time 25 min; splitless injection mode. Reproduced with permission from Sarrión *et al.* (1998). Copyright Elsevier Science.

as the ion trap mass spectrometer (ITMS). The addition of a water-miscible solvent, such as acetone (up to 30% v/v), to the water, which has previously been added to the soil sample, reduces the amount extracted into the fibre to within the linear dynamic range of the ITMS. The organic solvent also reduces the time required to reach equilibrium and allows shorter extraction times to be used. This is illustrated in Figure 5.

Using a 100 μm PDMS fibre, there was no significant difference seen in RSD values between headspace and direct sampling. A 7 μm PDMS fibre did show higher RSD values than the 100 μm PDMS fibre for headspace sampling. Using GC-ITMS analysis, the LODs were between 30 and 100 pg g^{-1} for the 100 μm fibre and headspace sampling. Headspace sampling gave a cleaner extract and resulted in a longer fibre life than the direct sampling method.

Comparison of SPME results obtained on a reference soil (CRM-530 or industrially contaminated clay soil) with results from other laboratories, mostly using Soxhlet extraction, showed good agreement for the mean values of the analytes.

Organometallics

Most SPME applications in the environmental field have been with organic pollutants. With the use of derivatization SPME, this has recently been extended to include some organometallic pollutants.

For heavy metals there is a strong dependence of the toxicity with the chemical form and the speciation of an element in a sample.

Sodium tetraethylborate (NaBEt_4) is a useful derivatizing agent for a number of organometallic compounds, including those of lead, mercury, cadmium,

tin and selenium. Using this reagent, derivatization can be performed in aqueous solution simultaneously with the extraction.

Optimal derivatization conditions were obtained at a pH of 5.3 using 1 mL of a 1% NaBEt_4 solution with 25 mL of sample. The rate-limiting step was the extraction into the fibre coating in the headspace extraction mode and not the derivatization.

Compromise extraction conditions were used of 10 min extraction time at 25°C. Longer extraction times increase the amount extracted, but 90% is extracted within the first 10 min. Increasing the extraction temperature increased the amount extracted for some compounds, but decreased the amount for others. As a result, 25°C was chosen, as it avoids the need for sample heating.

Using GC with inductively coupled plasma-mass spectrometry (ICP-MS) detection, LODs in the low parts per trillion were obtained, as shown in Table 2. The method has been applied to a standard reference material (NRC PACS-1, a marine sediment) to determine organotin content. A clean extract was obtained, as can be seen in Figure 6. The results for the dibutyl- and tributyltin showed good agreement with

the certified values and the values obtained via a classical liquid-liquid extraction.

The values for monobutyltin were significantly higher than the certified values. This has been reported as being a problem with the derivatization using NaBEt_4 for monobutyltin and is not attributed to any problems with the SPME part of the analysis.

Metal Ions

Inorganic metal ion analysis has also been achieved with SPME. In order to extract metal ions from aqueous solution, an unusual fibre constructed of a hydrophobic microporous polypropylene material was used. This fibre had a film thickness of $30 \mu\text{m}$ and 30% of the surface area was covered with pores of dimensions $0.05 \times 0.15 \mu\text{m}$. In order to extract mercury(II) ions from aqueous solution, dibenzo-18-crown-6 (DBC) was absorbed from solution into this hollow fibre and then this DBC-filled fibre was used for the extraction.

Separation of uncomplexed DBC from the DBC-mercury(II) complex was achieved by normal-phase HPLC with UV detection. The extraction equilibrium between the fibre and the solution with DBC was reached in under 30 s. This is a very rapid equilibrium for SPME. The time to reach equilibrium for the mercury(II) ions between the treated fibre and aqueous

solution was significantly longer; equilibrium was not reached after 1 h. In order to keep extraction time closer to the HPLC analysis time, 10 min extraction was used. With this extraction time and UV detection, the LOD for mercury(II) ions was around 500 p.p.b. The use of a more sensitive detection technique should significantly reduce this LOD.

The effectiveness of the extraction can be seen in Figure 7. No reports on the selectivity of this technique for metal ions have been published and this remains a key area for the future.

Future Developments

SPME is currently poised to become one of the major sample preparation methods for aqueous environmental samples in the future. The advantages that it offers, such as ease of use, no solvent and no plugging, make it a potential replacement for many of the liquid-liquid and SPE methods currently used. The expansion of SPME to the analysis of other analytes which are currently difficult to partition into the fibre coatings is another expected trend. This may be achieved by the development of new fibre coatings or by coupling existing coatings with derivatization or complexation reactions.

The future for SPME in the analysis of solids is less certain. Unless more robust SPME methods than those currently described are found, the replacement of Soxhlet extraction by SPME seems unlikely. Additionally, the problem of carryover is a cause for concern with the analysis of higher molecular weight analytes. Currently the cost of SPME fibres does not allow them to be used as single-use devices. This may, of course, change in the future and single-use fibres are the surest way to ensure that there is no carryover.

Introduction

The chemicals responsible for off-flavours, malodours and taints in foods and beverages can originate from incidental contamination from environmental (outside) sources (e.g. air, water, packaging material, a contaminated ingredient) and from chemical reactions occurring within the food material itself (e.g. lipid oxidation, enzymatic action, microbial metabolic reactions). In addition, imbalance off-flavours can occur when certain ingredient components that are normally present and often essential to the product are present in abnormally high or low concentrations.

When significant off-flavour problems occur, one of the first priorities of the food chemist is to identify any volatile or semivolatile organic chemicals that may be responsible. Once the identity of the off-flavour chemical(s) has been established, it is possible to speculate on its mechanism of formation and then decide on what corrective actions to implement to eliminate recurrence of the problem in the future.

Analytical Strategy for Studying Off-Flavours

The following steps are commonly used when trying to determine which chemicals in a particular food or beverage sample are the most important contributors to off-flavours:

- Extraction of volatiles/semivolatiles. The chemicals responsible for the food taint must be extracted and usually concentrated from the food matrix. This sample preparation step is critical to success. To isolate and evaluate potential chemical components that are responsible for the food taint, analytes must be separated from interfering chemicals in the food matrix.
- Injection into the gas chromatograph (GC: with or without cryofocusing).
- Separation of extracted volatiles on a GC capillary column with a suitable liquid phase. It is not uncommon to miss important polar compounds because the chemicals do not chromatograph well on nonpolar phases. Often the extraction technique is blamed, but the problem could simply be that an inappropriate analytical capillary column was used for the separation. One example is not detecting volatile fatty acids because separation was attempted on a nonpolar column.

- Determination of peak odour by olfactometry. It is often advantageous to sniff peaks as they elute from the GC column. The odour characteristics and intensities of the eluting peaks can help the analyst determine if the chemical is a likely contributor to the malodour or off-flavour. A variety of olfactometry detectors are commercially available; olfactometry detectors with heated transfer lines are highly recommended.
- Determination of which volatiles/semivolatiles are the most potent contributors to the product's odour. Gas chromatography-olfactometry (GCO) analysis has evolved over time to include dilution techniques (Aroma Extraction Dilution Analysis, AEDA and CharmAnalysis), cross-modal matching (Osme) and maximum perceived intensity. Of these three GCO modifications, extract dilution techniques and cross-modal matching have become the most common techniques used in analytical work on food flavours. Further discussion of the various GCO techniques is beyond the scope of this article.

Perhaps the most critical and challenging step in the process of characterizing the flavour of foods is the sample preparation technique used to isolate/concentrate the flavour compounds from the food matrix. Since it is not uncommon for the chemicals responsible for food malodours to be present at p.p.b. and even p.p.t. levels, the extraction technique must collect as many molecules of off-flavour chemicals as possible for GCO analysis. If the goal is to identify the chemicals responsible for an off-flavour, the sample preparation method selected should extract a representative profile of as many organic volatiles/semivolatiles from the sample as possible. On the other hand, it is also important that the extraction technique does not introduce or create volatiles that are not in the food product. For example, sample preparation techniques that involve heating the sample (e.g. steam distillation) can generate artifact peaks in sample chromatograms, and these odiferous artifacts may be misinterpreted as the cause of the malodour/off-flavour problem.

This article will discuss why solid-phase microextraction (SPME) is such an excellent extraction/concentration technique for the study of food off-flavours and taints.

Advantages of SPME as an Extraction Technique

Chemicals responsible for off-flavours can be polar, semipolar and nonpolar and cover a wide range of functional groups, boiling points and molecular

Table 1 General comparison of common analyte extraction techniques for studying food aromas (actual parameters vary depending on sample matrix, analyte, type of GC detector)

	Sample matrix	Sample size (g)	Detection limit	Range of volatiles analysed			Sample automation	Sample prep time (min)

^aCapable of analysing liquids, but usually requires binding of liquid portion of sample with an inert matrix material.

weights. As a result, no one analytical extraction/sample preparation method works in all cases. It is not uncommon that multiple sample preparation methods are required to identify the chemicals responsible for off-flavours and malodours in a particular sample.

Each sample preparation technique has advantages and disadvantages. The choice of a suitable sample preparation technique depends on several factors, including number of samples to be tested, how quickly results are needed, type of sample (matrix effects), the nature of the analytes of interest (i.e. functional group, molecular weight, boiling point, thermal stability, etc.), desired detection limits and required accuracy.

Table 1 compares a few popular extraction techniques used prior to GC analysis. Considering the wide range of sample sizes that can be analysed by

SPME, the low detection limits, the wide range of analyte boiling points that can be analysed, the fact that SPME can be automated and the short sample preparation time, it is no surprise that SPME is rapidly growing in popularity. The low cost of SPME equipment is also an advantage.

One often overlooked benefit of SPME is its high precision and accuracy compared to other GC sampling techniques. Studies comparing the precision and accuracy of SPME to other GC sampling techniques show that analytical results based on SPME extraction are often more precise and accurate than results based on other sample preparation techniques.

Several polar and nonpolar fibres with varying affinities for specific classes of compounds are now available. As a result, SPME fibre type can be selected in order to optimize results for a particular analyte class. Compounds that interfere with the

chromatography when the food extract is analysed by GC can be eliminated or at least minimized. If lipid oxidation is being studied, for example, the analyst could choose a Carboxen-PDMS fibre to measure aldehydes in the 1–500 p.p.b. range. If concentrations of aldehydes above 500 p.p.b. are present, the Carboxen-PDMS fibre will become saturated and a 100 μm PDMS fibre would be a better choice. A SPME fibre selection guide is shown in Table 2.

For some applications, the portability of SPME is an important advantage. After analytes are adsorbed on an SPME fibre, they can be maintained on the fibre for an extended period of time by sealing the end of the fibre with a septum. This allows for convenient field sampling. Perfumers have used this technique, for example, to extract aroma chemicals from flowers in greenhouses, as well as the fragrant chemicals from exotic flowers found in the canopy of tropical rainforests. Another example is a food chemist who is trying to determine if a malodour in a particular food product is being absorbed by the product because it has been stored near odiferous foods (e.g. spices) or perhaps industrial solvents. The food chemist can extract volatiles from the air in a warehouse or walk-in cooler with SPME, transport the SPME device with the trapped volatiles to the laboratory for GC analysis, and see if the GC profile matches the profile of a problem sample.

Retention characteristics are highly dependent on the fibre used and the volatility of the adsorbed analytes. Studies have shown that even highly volatile compounds can be stored on Carboxen-PDMS fibres for 3 days at room temperature without loss. The pore dynamics of Carboxen 1006 make it a true adsorbent. Retention of volatiles on 100 μm PDMS fibres, however, is not nearly as good. Even when fibres are stored at -4°C , only the least volatile analytes will be retained.

Specific Applications of SPME for Resolving Food Taints

The examples and case studies that follow illustrate the advantages of SPME as a sample preparation tool for the study of off-flavours and malodours in foods and beverages.

Light-Induced Off-Flavours in Milk: SPME vs. Headspace Analysis

Two types of light-induced oxidation reactions occur in milk and dairy products. Initially, a burnt, oxidized flavour develops and predominates for approximately 2–3 days. Dairy technologists refer to this off-flavour note as light-activated flavour (LAF). Degradation of sulfur-containing amino acids of the serum (whey)

proteins is probably responsible for this reaction. The exact reaction products for LAF have not been clearly elucidated. Methional [(3-methylthio)propanal], however, has been implicated as a possible contributor. Understanding the true impact that methional has on LAF is difficult to determine because it is relatively unstable and breaks down into more stable components, including mercaptans, sulfides and disulfides. Recently, researchers have postulated an alternative mechanism for the formation of dimethyl disulfide by singlet oxygen oxidation of methionine.

In addition to the poorly understood LAF off-flavour, a second type of light-induced off-flavour occurs in milk and is attributed to lipid oxidation. This off-flavour, often characterized as metallic or cardboard-like, usually develops after 2 days and does not dissipate. Aldehydes (especially pentanal and hexanal) and, to a lesser degree, ketones (e.g. 1-hexen-3-one and 1-nonen-3-one), alcohols and hydrocarbons have been observed to form in milk as a result of light-induced lipid oxidation reactions. When milk is exposed to light, various carbonyl compounds form from the reaction of light and oxygen with unsaturated fatty acids in the milk fat triglycerides and other milk fat components. Autoxidation of unsaturated fatty acids involves a free radical reaction, forming fat hydroperoxides that degrade to various malodorous compounds (e.g. hexanal, the predominant lipid reaction by-product in light-exposed milk in the case of linoleic acid).

In one recent study to quantitate pentanal and hexanal in light-abused milk (skim milk and 2% fat milk), a comparison was made using two different sample preparation techniques: dynamic headspace (DH) with a Tenax trap and SPME with a Carboxen-PDMS fibre. Results, which are summarized in Table 3, show that standard calibrations with SPME were more linear for both analytes in both types of milk samples than with DH. (Calibration was based on the method of additions technique using an internal standard of 4-methyl-2-pentanone.) Furthermore, the SPME method had about the same detection limit as the DH method. To test the precision of each method, four replicates spiked with 2 ng mL^{-1} of each aldehyde were compared for both types of milk samples. When coefficients of variations were calculated for this study, SPME proved to be more precise than DH.

For these particular samples and these particular analytes, SPME consistently demonstrated better precision without a sacrifice in sensitivity. Furthermore, none of the problems with carryover, background or artifact peaks that sometimes occur with DH systems were observed with the SPME experiments. No carryover peaks were detected in milk samples, even

Table 3 Comparison of the principal analytical parameters for pentanal and hexanal analysed by DH/GC-MS and SPME/GC-MS

Compound	Sample	Analytical technique	Detection limit (ng mL ⁻¹)	Repeatability of four replicates at 2 ng mL ⁻¹ (coefficient of variation, %)	Linear least-squares correlation coefficients ^a
Pentanal	Skim	DH	0.1	8.0	0.966
		SPME	0.1	1.9	0.990
Hexanal	Skim	DH	0.3	21.1	0.910
		SPME	0.5	7.1	0.995
Pentanal	2% Milk	DH	0.3	7.6	0.996
		SPME	0.3	2.1	0.999
Hexanal	2% Milk	DH	0.8	8.3	0.982
		SPME	0.8	4.9	0.993

^aFor calibration curve of five standards ranging from 0.0 to 30.0 ng mL⁻¹.

when injecting the SPME fibre immediately after it was used to analyse a milk sample spiked with high levels (500 ng mL⁻¹) of each of the following aldehydes: butanal, isopentanal, pentanal, hexanal, heptanal and octanal.

Because so many different parameters need to be optimized when performing DH and SPME experiments, care must be taken when comparing SPME and DH for precision, accuracy and sensitivity, and it is probably an over-simplification to say that one method is better than another. None the less, this work shows that SPME is a viable extraction technique for measuring oxidation products in milk and dairy products.

Highly Volatile Malodorous Chemicals

Highly volatile compounds can be responsible for off-flavours and malodours and can be difficult to trap and isolate. DH techniques with Tenax trapping often fail to trap and detect low molecular weight polar compounds. Static headspace works well for highly volatile chemicals but may not be sensitive enough for some applications.

SPME is an ideal extraction tool for highly volatile analytes. Consider, for example, the analysis of acetaldehyde in buttermilk. Acetaldehyde has a boiling point of 21°C.

Acetaldehyde in buttermilk The delicate flavour associated with high quality cultured buttermilk is contributed by several bacterial metabolites, including lactic acid, traces of acetic and formic acids, ethanol, diacetyl and carbon dioxide. Two different types of bacteria are used in buttermilk starter cultures: the acid-producing types (usually strains of *Streptococcus lactis* or *S. cremoris*) and the aroma bacteria (usually *Leuconostoc citravorum*). Diacetyl, the major flavour component of buttermilk, is produced by the fermentation of citric acid by the aroma-producing bacteria.

One common type of off-flavour in buttermilk is called the green flavour defect. It is caused by the loss of diacetyl (by conversion to acetyl methylcarbinol by diacetyl reductase enzyme in the culture bacteria) and an increase in acetaldehyde production. Measuring the acetaldehyde to diacetyl ratio is a good way to monitor this flavour defect.

As shown in **Figure 1**, SPME (e.g. Carboxen-PDMS) is an excellent way to extract acetaldehyde, diacetyl, acetic acid and other flavour-important metabolites from buttermilk. Even with SPME, however, it is necessary to use cryofocusing (typically at -100°C) after thermal desorption from the SPME fibre and prior to injection into the GC capillary column. With cryofocusing, sharp GC peaks are obtained for acetaldehyde; without cryofocusing, the acetaldehyde peak may not be detected at all.

1,3-Pentadiene from sorbate degradation Testing for 1,3-pentadiene in foods and beverages is another example of how SPME can be used to quantitate a highly volatile malodorous compound. Sorbic acid (2,4-hexadienoic acid) and its water-soluble potassium salt are commonly used as food preservatives to prevent yeast and mould growth. Foods in which sorbate has commercially useful antimicrobial activity include baked goods, cheeses and other dairy products, confectionery products, dried fruits, fish products, fruit juices, jellies (with artificial sweeteners), syrup, vegetables and wine.

One problem with potassium sorbate is that some moulds in the genus *Penicillium* can grow in the presence of up to (approximately) 1.2% potassium sorbate. Furthermore, some of these moulds have the ability to decarboxylate sorbic acid, producing 1,3-pentadiene, a highly volatile compound with an extremely strong hydrocarbon-like odour (typically kerosene-like).

As in the case of testing for acetaldehyde in buttermilk, using SPME with a Carboxen-PDMS fibre and

Figure 1 Volatiles in buttermilk by SPME (Carboxen-PDMS) extraction followed by GC-MS. Sample preparation: 2 mL of buttermilk, 7 μ L of internal standard solution (54 p.p.m. 4-methyl-2-pentanone), and a small magnetic stirring bar were added to a 4 mL GC vial and sealed. Headspace volatiles were extracted by SPME for 20 min at 50°C. Peak identities: 1, acetaldehyde; 2, acetone; 3, dimethyl sulfide; 4, diacetyl; 5, acetic acid; 6, 2-pentanone; 7, ethyl acetate; 8, internal standard; 9, butyric acid.

cryofocusing prior to release into the analytical column works well for measuring 1,3-pentadiene in foods and beverages. A chromatogram showing 1,3-pentadiene in a ready-to-drink refrigerated tea product is shown in **Figure 2**. A consumer complained that this particular tea sample had a kerosene odour.

High Boiling Point Compounds with Musty Odours

While extremely volatile compounds can be challenging to extract and isolate, so too are high boiling point semivolatile chemicals. Sometimes it is necessary to use combinations of sample preparation techniques to extract and isolate sufficient quantities of this type of malodorous compound from foods to achieve meaningful analytical results.

Algae, fungi, bacteria and *Actinomyces* are known to produce geosmin (GSM) and 2-methylisoborneol (MIB). These semivolatile, lipophilic compounds have a muddy, musty odour perceived as disagreeable to consumers. Both compounds are rapidly absorbed from water into the lipid tissue of fish and other aquatic organisms. When either compound is present in tissue at concentrations exceeding 0.7 μ g kg⁻¹, they render fish unfit for retail sale.

Current methods for quantifying the concentrations of MIB and GSM in catfish include: purge-and-trap-solvent extraction (P&T-SE); microwave distillation-solvent extraction (MD-SE) and microwave distillation-solid phase extraction (MD-SPE). These methods are time-consuming, labour-intensive and require the use of small quantities of flammable and/or toxic solvents or expensive microwave equipment. A faster and less expensive method could find broad application in catfish flavour research, the cat-

fish-processing industry and other aquaculture industries plagued by this problem.

Lloyd and Grimm, USDA research chemists, have developed a rapid and simple analytical procedure for quantitating low levels of GSM and MIB in catfish tissue. Their method combines microwave distillation (MD) with SPME. MD transfers lipophilic volatile analytes from the lipid-rich matrix of catfish tissue into an aqueous matrix, and SPME is then used to extract and concentrate the volatile organic compounds from the aqueous solution. The technique is a prime example of how combinations of two or more sample preparation techniques can be a potent strategy for resolving analytical problems that are inadequately addressed by a single sample preparation technique.

While SPME has been shown to be a sensitive, reproducible, quantitative sample preparation tool, the direct analysis of p.p.b. levels of GSM and MIB in fish tissue is not possible with SPME. Due to their lipophilic nature, MIB and GSM partition from fish tissue into the headspace in such low concentrations that direct SPME is ineffective. Combining MD with SPME yields a rapid, extremely sensitive technique for the analysis of thermally stable volatile and semivolatile compounds in complex matrixes. **Figure 3** is a schematic diagram of a typical MD-SPME apparatus for analysing MIB and GSM in fish tissue.

Mouldy/Musty Chemicals in Wine and Corks

Cork from *Quercus suber* has been used as a closure for wine bottles since the 17th century. Cork offers unique physical properties as a closure, including

Figure 2 Volatiles in tea with a kerosene-like off-flavour by SPME (Carboxen-PDMS) extraction followed by GC-MS. Sample preparation: 2 mL of tea and a small magnetic stirring bar were added to a 4 mL GC vial and sealed. Headspace volatiles were extracted by SPME for 20 min at 50°C. Peak identities: 1, acetone; 2 and 3, 1,3-pentadiene isomers; 4, 2-butanone; 5, pentanal; 6, 2-pentanone; 7, hexanal; 8, 4-methyl-6-hepten-3-one; 9, 2,3-dehydro-1,8-cineole; 10, hexyl acetate; 11, 1,4-cineole; 12, 1,8-cineole; 13, α -terpineol.

long-lasting flexibility, hydrophobicity and gas impermeability. Over the last two decades, the incidence of mouldy and musty off-flavours in cork-sealed wines has increased significantly. 2,4,6-Trichloroanisole (TCA) has been identified as the primary chemical responsible for cork taint. The human olfactometry threshold for TCA is 4–10 ng L⁻¹ in white wine and 50 ng L⁻¹ in red wine. In the case of wine, a worldwide loss of roughly US\$1 billion per year is attributed to cork taint.

The use of SPME fibres to extract TCA from the headspace over an agitated wine and moistened cork matrix is a short, inexpensive and solvent-free method to determine TCA. Due to the efficient adsorption properties of PDMS SPME fibres and the high sensitivity of GC-MS, the limit of detection of

2.9 ng L⁻¹ TCA is low enough to detect problem wine and cork samples that exceed the olfactory threshold range in wine of 4–50 ng L⁻¹.

Immersion of the SPME fibre into the wine was found to give poorer sensitivity and can increase contamination of the injector system and shorten the lifetime of the SPME fibre and analytical GC column.

Free Fatty Acids by Headspace and Immersion Techniques

Free fatty acids (FFAs), even at relatively low concentrations, are critical to both desirable and undesirable flavours in many types of food systems. Low levels of FFAs are difficult to detect in cheese and other food samples by dynamic or static headspace methods. SPME offers two alternative approaches to determine

Figure 3 MD-SPME apparatus for analysing 2-methylisoborneol and geosmin in fish tissue.

Table 4 Linearity of responses for free fatty acids using immersion SPME (50 p.p.b.–25 p.p.m.)

<i>Acid</i>	<i>% RSD of response factor</i>
Acetic	140
Propionic	16.1
Isobutyric	14.4
Butyric	18.9
Isovaleric	12.1
Valeric	14.2
Hexanoic	9.1

these compounds in cheese: the solid sample can be warmed for headspace sampling, or the sample can be liquefied for sampling by immersion SPME. Shirey, Supelco's SPME applications chemist, investigated both approaches for monitoring FFAs in cheeses using varied extraction conditions.

The headspace SPME approach offered the greatest sensitivity for these analytes, but immersion of the fibre into the liquefied samples produced the widest range of linear responses. Under all conditions, acetic acid was particularly difficult to quantify (Table 4).

The following conditions were used for the analysis of Parmesan cheese for FFAs: sample: 100 mg cheese in 40 mL vial; SPME fibre: 65 μ m Carbowax®/divinylbenzene StableFlex™; extraction method: headspace for 15 min at 65°C; desorption: 1 min at 250°C.

Sanitizer Contamination in Milk

The food and beverage industry is now less dependent on chlorine-based sanitizers for disinfecting processing equipment. Because application does not lead to toxic halogenated organic compounds, peroxyacetic acid (PAA)-based sanitizers are now widely used for disinfection in cleaning-in-place (CIP) systems in breweries and dairies. One problem with PAA-based sanitizers, however, is that even small amounts of PAA contamination can lead to severe off-flavours in milk. This problem can occur if sanitizers are not completely rinsed from processing lines prior to processing the next load of milk.

PAA, which can be quantitated in milk by HPLC after derivatization with methyl *p*-tolylsulfide, has a half-life in milk of approximately 20 min. As a result, PAA concentrations normally fall below threshold taste limits after only a few hours, even in milk contaminated with relatively large quantities of PAA. Once milk is contaminated with PAA, however, there is a significant off-flavour that fails to dissipate over time. The PAA-induced reactions that lead to this off-flavour defect are not well understood but probably involve oxidation of the milk proteins by PAA and/or hydrogen peroxide. To determine if an

off-flavour in milk has occurred because of PAA contamination, one approach is to check acetic acid levels, since PAA degrades to water and acetic acid. Headspace SPME with a Carboxen-PDMS or a Carbowax-divinylbenzene StableFlex fibre is capable of detecting p.p.b. levels of acetic acid in milk.

One popular sanitizer used by some dairies is Matrixx™ (Ecolab, St Paul, MN). Matrixx has the following composition (approximate): 4.4% PAA, 6.9% hydrogen peroxide and 3.4% octanoic acid. Figure 4 shows chromatograms of a control milk sample (no off-flavour) and a sample with a severe off-flavour that was suspected to be caused by contamination with Matrixx. Peaks for acetic and octanoic acids are indicators that the sample is contaminated with Matrixx sanitizer. The following conditions were used for the analysis: sample: 2 mL of low fat milk + 1 mL 0.1-N phosphoric acid + 1 g salt in a 9 mL vial; SPME fibre: 65 μ m Carboxen-PDMS; extraction method: headspace (with stirring) for 12 min at 40°C; desorption: 2 min at 250°C. The analytical capillary column was FFAP™ (Free Fatty Acid Phase).

Off-Flavours from Packaging Materials

Ironically, packaging materials, which are designed to preserve the freshness and flavour of foods and beverages, can be directly responsible for causing off-flavour defects. Although plastic packaging material consists primarily of nonvolatile high molecular weight polymers, volatile low molecular weight compounds are often added to improve functional properties of the materials: plasticizers to improve flexibility, antioxidants to prevent oxidation of the plastic polymers and the food inside the packaging and UV blockers to prevent yellowing of polymeric material when it is exposed to light. Additional additives include polymerization accelerators, cross-linking agents, antistatic chemicals and lubricants.

Occasionally, packaging materials are not adequately cured before they are used. As a result, a small amount of solvent associated with the manufacturing of the packaging materials or from the inks and dyes used on packaging graphics remains and is absorbed by the food material inside the package.

Screening packaging material for undesirable residual solvents is a simple task with SPME. Figure 5 shows volatiles extracted from the headspace of a closed, new (unused) cottage cheese carton (680 g fill weight). The lidstock is a linear low density polyethylene (Dow 2503 resin), and the container body is polypropylene (Montell copolymer). The volatiles were sampled simply by poking a pinhole through the top of the closed container and inserting an SPME fibre (Carboxen-PDMS) through the hole. A small magnetic stirring bar was placed inside the carton to

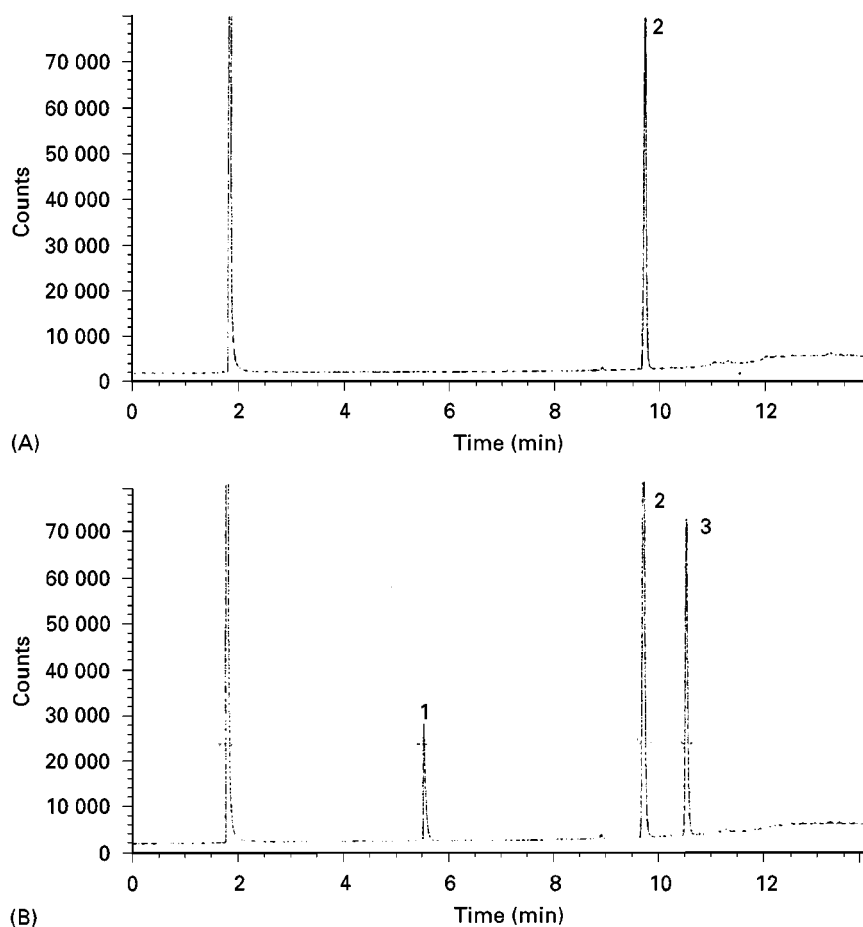

Figure 4 (A) Low fat milk control and (B) complaint low fat milk with off-flavour. Peak identities are as follows: 1, acetic acid; 2, internal standard (2-ethylhexanoic acid); 3, octanoic acid. Complaint sample is contaminated with 0.11% Matrixx sanitizer. Concentration of octanoic acid is 37 p.p.m. See text for details of method.

facilitate air movement over the fibre. The fibre was exposed to the atmosphere in the carton for 30 min at room temperature. A large number of volatiles was

detected. Nearly all peaks detected were hydrocarbons of various chain lengths. However, a significant amount of trichloroethylene was also detected.

Figure 5 Volatiles extracted from the headspace of a closed, new (unused) cottage cheese carton (680 g fill weight) by SPME. Peak no. 1 is trichloroethylene; most of the other chromatographic peaks are alkanes. See text for details of method.

A few types of malodorous packaging solvents that have been found to cause off-flavours in foods include styrene, ethylstyrene, trimethylbenzene isomers and propyl acetate.

Pesticides in Wine

Not all food taints involve odiferous chemicals that contribute to off-flavours. Contamination of foods with pesticides is another type of food taint of critical concern. Wine is one type of beverage that can be contaminated with pesticides.

Procymidone fungicide Procymidone is a fungicide which is widely used against *Botrytis cinerea* on wine grapes. If improperly applied, undesirable residues at concentrations ranging from a few p.p.b. to several hundred p.p.b. can be found in wine after fermentation and even in old bottles because of its well-known persistence. The standard analytical sample preparation method for testing procymidone in wine is based on time-consuming liquid-liquid extraction or solid-phase extraction (SPE) using polymeric bonded silica cartridges.

Urruty and co-workers at the Université de Bordeaux (Périgueux, France) found that SPME (100 μ m PDMS) results for procymidone in white and red wine correlated very well to ELISA test results. SPME was as fast as ELISA and offered slightly better precision.

Methyl isothiocyanate soil fumigant Another chemical of concern to wine makers is methyl isothiocyanate (MITC). It is used as a soil fumigant for nematodes, fungi and other diseases in vegetables and fruits. MITC is illegally employed as an antifermentative substance in wines. The addition of antifermentative agents in wines is controlled by EC and non-EC regulations. In particular, the Italian legal system does not allow the use of MITC in wines and requires the control of all exported wines. Solvent-solvent extraction is the traditional sample preparation method for measuring MITC in wines.

Grandini and Riguzzi (Bologna, Italy) compared SPME with the official Italian method. The SPME fibre used was Carbowax-divinylbenzene (65 μ m). For SPME, headspace sampling of 5 mL of wine in a 10 mL vial was conducted for 30 min; 1.25 g of sodium chloride was added to the sample.

The lengthy standard sample preparation for MITC in wine was as follows: a 100 mL sample of wine was spiked with 100 μ L 4-ethylpyridine (internal standard). The pH of the wine was adjusted to 7 with sodium hydroxide. The sample was then extracted three times with 15 mL of pentane. Anhydrous sodium sulfate was added to the solvent, which was then concentrated to 0.3 mL with a rotary

evaporator at 40°C. No vacuum was applied, in order to minimize MITC loss.

SPME-GC with a nitrogen-phosphorus detector (NPD) gave a minimum detectable limit of 1 p.p.b. and a linear detector response in the 1–200 p.p.b. range. Although many methods use the NPD, including the official method, they are not able to obtain minimum detectable limits of less than 10 p.p.b. Compared to the official method, SPME offered the following advantages: low minimum detection limits, wide linearity range, short analysis time and low costs. Furthermore, sample pretreatment is eliminated and solvents are not used.

Quality Control (QC) Applications: SPME-MS-MVA as an Electronic Nose

The combination of SPME with GC and mass spectrometry-olfactometry detection is a potent tool for understanding the causes of food off-flavours, malodours and taints. However, the complexities involved in performing capillary GC testing, as well as the difficulties associated with the interpretation of results, require highly trained chemists. Furthermore, the technique is time-consuming and not amenable to the rapid product evaluation and decision-making that is often required in quality control situations. Even with assistance from peak recognition software that matches corresponding peaks in different chromatograms, the large number of GC peak data associated with flavour/off-flavour studies of food systems is time-consuming and prone to errors. As a result, SPME-GC-MS-OD is essentially a tool for research and development chemists and chromatographers.

Advantages of SPME-MS-MVA for QC Applications

There is, however, a relatively new SPME-based technique that has proved useful for food quality control applications. The technique has been referred to as SPME-MS-MVA (solid-phase microextraction-mass spectrometry-multivariate analysis). Essentially, the analytical system is an electronic nose (e-nose) in which a mass spectrometer replaces the typical chemical sensor array, and SPME replaces static or dynamic headspace sampling as the extraction technique to introduce volatiles/semivolatiles to the detector. The GC is used, with the only modification being the substitution of the typical 30 m coated capillary column with a 1 m uncoated fused silica column.

The speed, simplicity, sensitivity, portability and relatively low cost of SPME make it an ideal extraction technique for introducing volatiles and semivolatiles to the e-nose detector. With multiple manual SPME set-ups, it could be possible to analyse

one sample every 3 min using the same GC-MS system. Another advantage of using SPME as a way of introducing volatiles into the e-nose detector is that different fibres can be selected for different applications (see Table 2).

Using a mass spectrometer as a chemical sensor is advantageous because it is sensitive and robust, does not suffer from memory effects, and is not poisoned by low levels of moisture injected from SPME extractions. Furthermore, unlike typical commercial e-nose chemical sensors based on conducting polymers, metal oxides, surface acoustic wave (SAW) devices, quartz crystal microbalances (QCMs), or combinations of these devices, reliable easy-to-use benchtop MS detectors have been in routine use for decades and have a proven track record.

Another advantage of SPME-MS-MVA is that it can easily be converted to SPME-GC-MS simply by replacing the 1 m uncoated fused silica transfer line with an appropriate 30 m coated capillary GC column. Researchers can then perform more detailed traditional analyses, including identification and quantitation of specific odour-active GC peaks. This approach can be extremely helpful in determining what masses to monitor (as well as what masses to exclude) for specific e-nose application using MS as the chemical sensor.

Specific SPME-MS-MVA QC Applications

With SPME-MS-MVA, the ability to identify individual chemical components is lost. However, the trade-off is the gain in speed and simplicity of interpretation of results. The technique is rapid and generally gives comparative rather than quantitative information. It is ideally suited for quick quality assurance (QA)/QC screening.

SPME-MS-MVA generates mass intensity tables for each sample tested. The mass intensity data used to prepare the principal component analysis (PCA) scores plots in Figures 6 and 7 were obtained in the following manner:

1. Sample volatiles were extracted using SPME (65 μ m Carboxen-PDMS) and desorbed from the SPME fibre by the heated GC injection port (250°C) into a 1 m deactivated fused silica transfer line heated to 50°C.
2. Data acquisition (from m/z 50 to m/z 150) was discontinued after 2 min.
3. The masses of the single resulting chromatographic peak generated by the ion fragments from headspace volatiles of the sample were averaged from 8 to 80 s, while masses from 0 to 7 s and from 81 to 100 s were subtracted as background.

Figure 6 Principal component analysis scores plot of mass intensity data for control and light-abused soybean oils as determined by SPME-MS-MVA. Soybean oil: days of fluorescent light exposure (200 FC). 0, 0 days; 4, 4 days; 7, 7 days; D7, 7 days in the dark.

4. The resulting mass intensity list provided the data used for PCA.

Two QA/QC examples of SPME-MS-MVA are provided below.

Off-flavour development in soybean oil exposed to light Deodorized commercial soybean oil was exposed to fluorescent light for different time periods and analysed by SPME-MS-MVA. Prior to extraction, the soybean oil was placed in a 50 mL Nessler tube and exposed to 200 foot candles (FC) of fluorescent light. Four different types of samples were analysed: control soybean oil (fresh oil, normal taste, no light exposure); control oil exposed to light for 4 days; control oil exposed to light for 7 days; and a Nessler tube filled with control oil, wrapped in aluminium foil, and stored alongside the

Figure 7 Principal component analysis scores plot of mass intensity data for fresh boiled beef and boiled beef refrigerated for 4 days and 6 days and then reheated. Results generated by SPME-MS-MVA technique. 0, 0 days (freshly boiled); 4, 4 days storage at 4°C; 6, 6 days storage at 4°C.

light-exposed oils for 7 days. All Nessler tubes were sealed with Parafilm® and stored at 22°C. Six samples of each type were prepared and analysed, except for the 7-day-old sample stored in the dark (i.e. wrapped in foil); only three samples of this treatment were analysed.

SPME procedure 2 g soybean oil was added to a 9 mL glass GC vial and capped with a polytetrafluoroethylene septum closure. Samples were heated to 45°C in a water bath and stirred vigorously with a small stirring bar while the SPME fibre was exposed to the headspace vapours in the vial for 12 min.

Results The PCA scores plot for this set of samples appears in Figure 6, which shows that SPME-MS-MVA is capable of grouping together samples of soybean oil that have been exposed to similar levels of light abuse.

Warmed-over flavour (WOF) in boiled beef A beef sample (500 g of chuck roast) was boiled for 60 min in a water bath. The internal temperature of the beef reached 92°C. Immediately after boiling, the hot meat was ground in a meat grinder, split into six separate samples and analysed by SPME-MS-MVA. After storage at 4°C for 4 days, the samples were reheated to 50°C in a convection oven for 30 min. Organoleptic evaluation of the samples showed that their flavour had changed from a typical beef flavour to an off-flavour characterized as tallowy, green and metallic. Samples were again refrigerated, stored for an additional 48 h, and re-analysed after warming to 50°C.

Figure 8 Development of warmed-over flavour in cooked beef. SPME-GC-MS chromatogram of boiled beef (A) at 0 days and (B) after 6 days of storage and then reheated to 50°C. Peak identities: 1, pentanal; 2, hexanal; 3, heptanal; 4, 2,4-nonadienal; 5, octanal; 6, 2,3-octanedione; 7, nonanal; 8, 1-octen-3-ol; 9, 2-heptenal.

Samples after 6 days of storage developed even stronger WOF notes.

SPME procedure 0.5 g boiled beef (ground) plus 2.5 mL water were added to a 9 mL glass GC vial. All other conditions were the same as the soybean oil SPME procedure given above.

Results The PCA scores plot for this set of samples appears in Figure 7. SPME-MS-MVA is capable of identifying groups of samples with similar levels of WOF.

To ensure that SPME was measuring volatiles that are known to contribute to WOF (e.g. aliphatic aldehydes, 2,4-nonadienal, etc.), a fresh boiled beef sample (0 days) and a 6-day sample were analysed by SPME-GC-MS. The resulting chromatograms, shown in Figure 8, prove that SPME is extracting compounds that have been identified as the source of WOF by other researchers. The chromatogram was generated using the identical method used for SPME-MS-MVA, with the exception that the 1 m transfer line was replaced with a 30 m FFAP capillary column.

Conclusion

As the numerous examples in this article illustrate, SPME is one of the most potent extraction, isolation and concentration techniques available for studying off-flavour chemicals in foods and beverages. Improvements in SPME technology will probably be made in the near future, making the technique even more useful to flavour chemists. Important recent developments in fibre technology include:

1. StableFlex™ fibres (which exhibit greater flexibility and increased strength compared to previous fibres);
2. a highly cross-linked PDMS fibre coating to minimize bleed and improve thermal stability;
3. coatings containing micro-adsorbent beads for retention and selectivity for many polar and volatile analytes;
4. dual-coated fibres that have the ability to efficiently extract low levels of both polar and nonpolar analytes in the same sample.

Introduction

Solid phase microextraction (SPME) has been applied to a diverse range of analytes and sample types. The growth in the application of SPME, since its inception in 1990, can be seen in **Figure 1** (information from the *Science Citation Index*, February 1999). SPME is used as both a method of preconcentration and as a sampling device for (predominantly) chromatographic analysis. SPME has been used in conjunction with a range of other techniques, such as, ultraviolet and infrared spectroscopy, Raman spectroscopy and mass spectrometry, but it is its use in chromatographic analysis which is the focus of this article. SPME has most commonly been coupled to gas chro-

matography (GC), although some applications have coupled it to high-performance liquid chromatography (HPLC) (**Figure 2**). The following discussion will concentrate primarily on the use of SPME coupled with GC.

The SPME device consists of a fused silica fibre, coated with a stationary phase (**Table 1**) and mounted in a syringe-type holder (**Figure 3**). The SPME holder has two functions: to provide protection for the fibre and allow insertion into the hot environment of the GC injector using a needle. As samples and standards are normally introduced into a GC via a syringe the use of this device offers no additional complexity.

At rest the fused silica-coated fibre is retracted within the protective needle of the SPME holder. In operation however, the fibre is exposed to the analyte within its matrix (air, water, solid) for a predetermined amount of time. The active length of the fibre is typically 1 cm. Two common approaches for sample extraction are employed; direct and headspace (**Figure 4**). The first involves direct contact between the coated fibre and the sample matrix; in this way analytes within the sample are able to be transported to the fibre coating. This transportation can be achieved by several means. In the case of liquid (or solid samples that have been mixed with an aqueous solution, i.e. a slurry), transportation is achieved by agitation of the sample vial, agitation of the fibre, stirring or sonication of the sample solution. For gaseous samples, natural convection is usually sufficient. In the headspace mode, the process relies on the release of volatile compounds from the sample matrix. This may be achieved by heat, chemical modification or the inherent volatility of the analyte.

After sampling, the fibre is retracted within its holder for protection until inserted in the hot injector

Figure 1 Frequency of SPME publications per year (information from the *Science Citation Index*, February 1999, Copyright International Scientific Communications, Inc.).

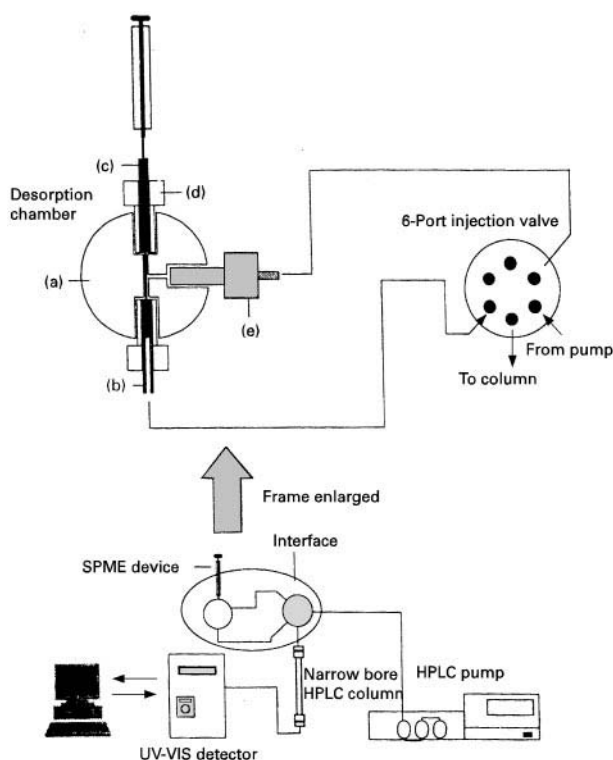

Figure 2 Solid phase microextraction-high-performance liquid chromatography interface (reproduced with permission, from *Analytical Chemistry* 67: 2530, 1995, Copyright American Chemical Society).

of the GC or mobile phase of the HPLC; desorption of analytes occurs due to the influence of temperature (GC) or organic solvent (HPLC). In either case the fibre is exposed for a particular time to allow for effective desorption of the analytes. As the coating on the fibre is selective towards the analyte, it is common to find that no solvent peaks are present in the subsequent chromatograms. As the fibre coating is selective towards the target analytes it is important to select the most appropriate fibre coating for the sampling process. **Figure 5** compares the influence of three fibre coatings, i.e. polystyrene-divinylbenzene (XAD), polyacrylate, and polydimethylsiloxane (PDMS) for the extraction of 49 organophosphorus pesticides from a water sample. The selectivity of each fibre coating is evident from the chromatograms (Figure 5).

It is important to note that the fibre can equally adsorb analytes from the atmosphere as well as the sample (in some cases the atmosphere may be the sample). Extreme caution should be taken first of all to clean the fibre. This can be done, for example, by exposing the fibre to the hot injector of the GC before sampling. Also, it is important to minimize the time between the sorption step and the subsequent desorption and analysis step.

Table 1 Commercially available fibre coatings

•	7 μm Polydimethylsiloxane (bonded)
•	30 μm Polydimethylsiloxane (non-bonded)
•	100 μm Polydimethylsiloxane (non-bonded)
•	85 μm Polyacrylate (partially crosslinked)
•	60 μm Polydimethylsiloxane/divinylbenzene (partially crosslinked)
•	65 μm Polydimethylsiloxane/divinylbenzene (partially crosslinked)
•	75 μm Polydimethylsiloxane/Carboxen (partially crosslinked)
•	65 μm Carbowax/divinylbenzene (partially crosslinked)
•	50 μm Carbowax/Template resin (partially crosslinked)

Quantitation in SPME is achievable in much the same way as for any other sample analysis. For example, in GC a series of standard solutions are prepared in organic solvent over the appropriate concentration range for the analytes under investigation. From the results obtained a calibration graph can be constructed [a plot of signal intensity (area or peak height) versus concentration]. Then, an organic solvent extract of the unknown is injected into the GC and its response compared to the calibration graph. In the same manner for SPME, a series of standard solutions need to be prepared in aqueous solution or soil slurry form. The fibre is then exposed to the solution (or soil slurry) for a prespecified time and then introduced into the hot injector of the GC. In

Figure 3 Solid phase microextraction device (reproduced with permission from *Analytical Chemistry* 66: 844A, 1994, Copyright American Chemical Society).

Figure 4 Common approaches for SPME. (A) Direct SPME and (B) headspace SPME.

this manner a calibration graph can be constructed. Similarly, an aqueous SPME extract (or slurry extract) of an unknown sample is injected in the GC and its signal response compared with the calibration graph. Calibration is also done in this manner for headspace SPME, the difference being that the fibre is exposed to the headspace above the sample only and not placed in the solution or soil slurry itself. It is common practice to utilize an internal standard for all quantitative analysis. Calibration is also possible using the method of standard additions. For further information on quantitative headspace methods see the book by Kolb and Ettre listed in the Further Reading section.

The diversity of applications of SPME is continually expanding, limited only by people's ingenuity, so it is not unfamiliar to find applications of SPME in such diverse areas as environmental and clinical, food and pharmaceutical, forensic and military use. However, the most popular application area is environmental analysis (water and soil). In order to provide examples of the diversity of applications, selected areas have been considered. For further information, the reader is recommended to consult the Further Reading Section or the current scientific literature.

Extraction of Analytes from Aqueous Matrices

Analysis of polar and labile analytes in aqueous matrices usually involves extraction and preconcentration. This has traditionally been based on

liquid-liquid extraction (LLE). In this context, a small volume of organic solvent is added to a larger volume of the aqueous sample and shaken (it may be necessary to 'salt-out' the analytes, this is done by saturating the aqueous sample with an inorganic salt). The organic phase containing the analytes is then analysed. [Note: additional preconcentration may be required using evaporation in a stream of inert gas (manual or automated) or vacuum evaporation.] However, if the analytes are sufficiently volatile they can be purged from an aqueous sample using a gas, such as nitrogen, preconcentrated by trapping on a suitable sorbent, e.g. Tenax, at low temperature and eluted by rapidly heating the trap. The analytes are then directly transferred into a gas chromatograph for separation and detection. This procedure, known as dynamic headspace or 'purge and trap' sampling is an effective procedure for volatile analytes. An alternative to the requirements for extraction and preconcentration of non-volatiles is solid phase extraction (SPE).

SPE uses a stationary phase, such as C_{18} -silica, to adsorb analytes from a large volume of sample solution. Elution of analytes is then achieved by using a small volume of organic solvent. In this manner, effective extraction and preconcentration is achieved. The use of SPME takes this method a stage further in miniaturization.

Effective extraction and preconcentration of analytes in aqueous matrices can be achieved using SPME. Two approaches are commonly used. In the first approach, the fibre is inserted directly into an aqueous sample for a prespecified time, with or

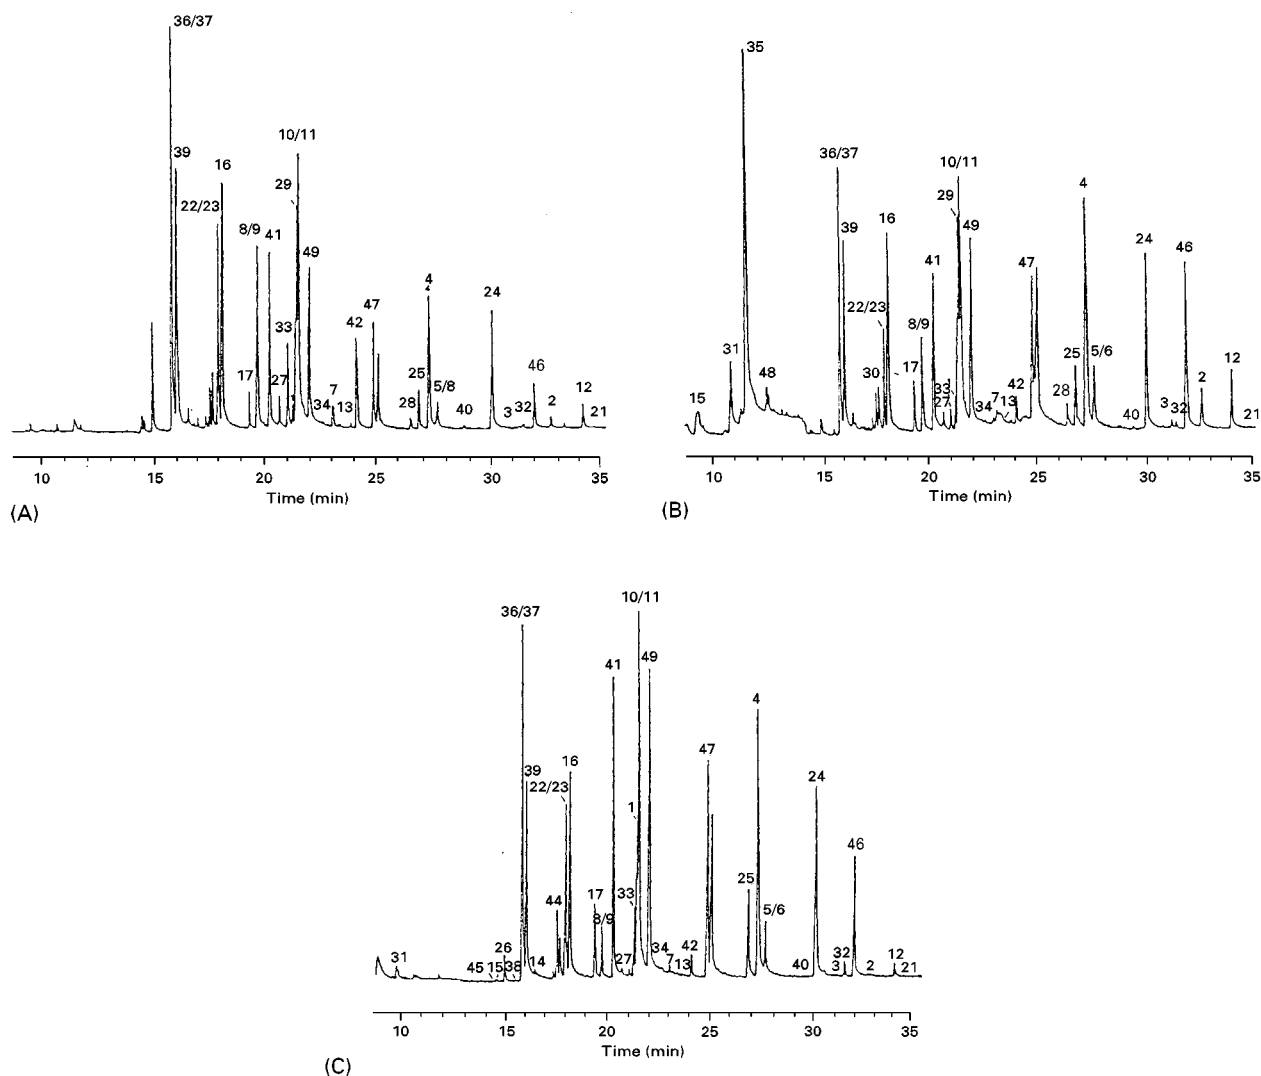

Figure 5 SPME of $3 \mu\text{g L}^{-1}$ organophosphorus pesticides. (A) $15 \mu\text{m}$ XAD polystyrene-divinylbenzene-coated fibre, (B) $85 \mu\text{m}$ polyacrylate-coated fibre, and (C) $30 \mu\text{m}$ polydimethylsiloxane-coated fibre. without stirring and with or without the addition of salt. The fibre is then retracted into its protective holder and the adsorbed analytes desorbed in either the hot injector of the GC or in the mobile phase of an HPLC system. This approach is to be favoured for the more non-volatile, labile type of analytes. The alternative approach is to place a small volume of the

liquid sample in a sealed vial and to insert the fibre into the headspace above the sample for a prespecified time. Again, stirring may be beneficial as well as the addition of salt. In addition, warming the sample vial may prove to be beneficial by increasing the concentration of volatile analytes in the headspace above the sample.

Direct Extraction

Examples of the direct approach have allowed multiple analytes, e.g. pesticides, to be determined in aqueous samples. For example, limits of detection for the determination of pesticides in water by GC with flame ionization detector (FID), nitrogen-phosphorous detector (NPD) or mass spectrometer (MS), using a $95\ \mu\text{m}$ polyacrylate-coated fibre, are shown in Table 2. Other SPME conditions are as follows: a 50 min equilibration time with stirring at room temperature; and desorption by inserting the fibre into the hot GC injector (250°C) for 5 min. Similarly, selected detection limits for a $100\ \mu\text{m}$ polydimethylsiloxane fibre are shown in Table 3. A typical SPME–GC–NPD chromatograph for the analysis of drinking water spiked with 36 pesticides (EPA Method 507) at the $10\ \mu\text{g L}^{-1}$ is shown in Figure 6. In addition, to evaluating the sensitivity of SPME by determining detection limits, an alternative approach is to evaluate the performance of SPME against a traditional aqueous extraction procedure (liquid–liquid extraction). Results for the extraction

of 20 organochlorine pesticides extracted from a groundwater sample by both SPME and LLE are shown in Figure 7. In the case of SPME, a $30\ \mu\text{m}$ polydimethylsiloxane fibre was inserted in a sample volume of $1.5\ \text{mL}$ for 20 min. Desorption was achieved by insertion into the GC injector for 10 min at 260°C . The spiking level was $1\ \mu\text{g L}^{-1}$. For LLE a $100\ \text{mL}$ sample spiked at the $0.5\ \mu\text{g L}^{-1}$ level was extracted with $20\ \text{mL}$, then $10\ \text{mL}$ of hexane. The combined extracts were dried with anhydrous sodium sulfate and concentrated to $1\ \text{mL}$ using a stream of nitrogen prior to analysis. In most cases similar results were obtained by SPME and LLE. Anomalous results for endosulfan I and II were reported.

Examples of the direct approach for non-volatile compounds, using SPME–HPLC, are shown in Figures 8 and 9. In Figure 8, a comparison is made between SPME and a $1\ \mu\text{L}$ loop injection for the analysis of polycyclic aromatic hydrocarbons (PAHs) using reversed phase HPLC. Using the SPME–HPLC interface, as shown in Figure 2, thirteen PAHs have been analysed after sampling for 30 min using a $7\ \mu\text{m}$ PDMS-coated fibre. Some differences, in terms of peak height, are noted (Figure 8) for peaks 1–4 when SPME is compared with direct injection. These differences are attributable to the selectivity of sampling associated with SPME. The versatility of the SPME–HPLC approach is further highlighted in Figure 9. In this case, an alkylphenol ethoxylate (Triton X-100) in the aqueous phase is sampled for 60 min with stirring

(*American Chemical Society, Analytical Chemistry*, 67: 2530, 1995.) HPLC conditions: column, 25 cm \times 2.1 mm internal diameter, 5 μ m ODS; flow rate, 0.2 mL min⁻¹; (detection, UV 254 nm; solvent programme, acetonitrile–water (80 : 20, v/v) linear gradient to 100% acetonitrile in 15 min. SPME conditions: 7 μ m polydimethylsiloxane fibre; adsorption time, 30 min with stirring. Spiking level was 100 ppb. Peak identification: 1 = acenaphthylene, 2 = fluorene, 3 = phenanthrene, 4 = anthracene, 5 = pyrene, 6 = benz[a]anthracene, 7 = chrysene, 8 = benzo[b]-fluoranthene, 9 = benzo[k]fluoranthene, 10 = benzo[a]pyrene, 11 = dibenzo[ah]anthracene, 12 = indeno[1,2,3-cd]pyrene, and 13 = benzo[ghi]perylene.

the aqueous phase. For this approach to be useful the analytes of interest must partition favourably into the vapour phase. Therefore, the approach is useful for volatile organic compounds in aqueous samples. Most work has been done with the BTEX compounds, i.e. benzene, toluene, ethylbenzene and the xylene isomers.

Samples and standards are introduced into glass vials, e.g. 40 mL volume, with Teflon-lined septa. It is beneficial for the speed of extraction to add a (Teflon-coated) stirring bar and/or salt for 'salting-out' to

improve sensitivity. Then, each vial is capped. The septum is then pierced and the SPME device inserted. The exposed coated-silica fibre is positioned approximately 1 cm above the surface of the aqueous sample. The entire assembly is mounted on a magnetic stirring plate. Care is required during the stirring process that the vortex generated is not so vigorous so that the aqueous sample comes into contact with the exposed fibre (a vortex of depth 1 cm is adequate). In addition, the sample vial may be heated, by placing it in a temperature controlled water bath at temperatures in the range 40–80°C. The extraction time can be varied between 5 and 50 min, as desired. After a suitable exposure time, the fibre is retracted into its holder, withdrawn from the vial and immediately inserted into the hot injector of the GC for subsequent separation and detection. The typical performance of this type of headspace SPME is summarized in Table 4. The results in Table 4 compare the statistical detection limits obtained by both the headspace SPME and purge and trap approaches. In both cases, the statistical detection limits were approximately an order of magnitude higher than those required for the analysis of drinking water (US EPA Method 524.2). The use of a more sensitive detector, for instance an ion trap mass spectrometer, could lower the detection limits achievable.

Extraction of Analytes from Solid Matrices

Traditional approaches for the extraction of analytes include Soxhlet extraction (and its variants), shake flask extraction and sonication. Soxhlet extraction is frequently referred to as the benchmark technique, so it is not surprising to find that results obtained with newer extraction techniques are compared to data obtained by Soxhlet extraction. While Soxhlet is used as the method of choice for many people for extracting analytes from solid matrices, it is a time-consuming process and uses relatively large volumes of organic solvent. Alternatives have therefore been sought to produce analytical data more rapidly and that use smaller amounts of organic solvent (or none at all). In this context, alternatives that have been proposed include supercritical fluid extraction, microwave-assisted extraction and pressurized fluid extraction. However, the high capital cost of all these alternatives and in some cases the level of expertise required to operate the instruments effectively has precluded their wide acceptance. In this context, the use of SPME has been proposed. However, in order for SPME to be of any use, the analytes must be released from the solid matrix and enter either a liquid phase or the gaseous phase. Variants on these themes for SPME are now considered.

Figure 9 Normal phase HPLC chromatogram of extracted Triton X-100. Peak assignment refers to the number of units in the ethoxylate chain. (*American Chemical Society, Analytical Chemistry* 68: 1521, 1996.) HPLC conditions: column, 25 cm \times 4.6 mm internal diameter, 5 μ m Supelcosil LC-NH₂; flow rate, 1.5 mL min⁻¹; detection, UV 220 nm; solvent programme, 3–53%B, where A is 90 : 10, v/v hexane–2-propanol and B is 90 : 10, v/v 2-propanol–water. SPME conditions: carbowax/template resin fibre; adsorption time, 60 min with stirring at room temperature; desorption time, 1 min. Spiking level was 100 ppm. Sample volume was 4 mL.

Several approaches can be adopted for the extraction of analytes from solid matrices using SPME. These include direct extraction of the analytes from a soil–water suspension or slurry; extraction of the analyte from the sample matrix using hot water; or, headspace extraction. In the first two approaches, it is assumed that the analytes are highly soluble in water and that water is a suitable solvent to liberate the analyte from its matrix. The latter scenario assumes that the analytes of interest are volatile or semi-volatile so that they are available in the headspace above the sample.

Table 4 Analysis of BTEX compounds from aqueous samples: determination of statistical method detection limits (μ g L⁻¹)^a

Compound	Headspace SPME ^b	Purge and trap ^c	EPA 524.2 ^d

Direct (Slurry) SPME

For slurry extraction, a known quantity of sample, e.g. 10 mg to 1 g of soil, is mixed with a solvent (water) and stirred. It may be necessary to adjust the pH of the solution (to convert all compounds to a non-ionized form) and add salt to improve the extraction efficiency. The SPME fibre is then exposed directly to the resultant suspension or slurry for a prespecified time (1–60 min) and then analysed. In addition, it also assumes that the matrix itself will not interfere with the extraction process. If this is the case, the SPME fibre can be placed inside a protective membrane in the slurry. The major limitation of this approach is that the membrane itself does not preclude any of the analytes of interest. However, this approach has not yet been fully tested and further evaluation is necessary. Typical results for the analysis of chlorophenols from a contaminated land site are shown in Table 5 using the slurry SPME approach and two methods of quantitation (direct calibration using an internal standard and the method of standard addition). The results are compared with those obtained by Soxhlet extraction. A typical SPME–GC–MS chromatogram of the soil sample is shown in Figure 10.

Combined Hot Water Extraction–SPME

An alternative to the slurry method is to extract the solid sample with hot water and then isolate the analytes from the water using SPME prior to chromatographic separation and detection. This is a relatively new approach with few relevant publications to date. The basis of the approach, however, is that hot, pressurized water can selectively leach analytes from the solid matrix. Early work has suggested that the water temperature needs to be above 200°C and a pressure of 50 atm for effective

^b SPME: 40 mg of soil in 12.5 mL of a $20 \mu\text{g L}^{-1}$ internal standard (2,4,6-tribromophenol) solution and, then solution was diluted to 50 mL with pH 1 buffer solution and 5 M KCl added.

^c Soxhlet: 2 g soil extracted with 150 mL of n-hexane-acetone (1 : 1) for 8 h. Analysis using GC-SIM-MS.

extraction of semi-volatile compounds of environmental interest including polycyclic aromatic hydrocarbons (PAHs). It is also important in this type of work to be vigilant for analyte degradation, which obviously might result in lower recoveries than expected (but also not to neglect the possibilities of formation of compounds of interest). The dynamic extraction of organic pollutants from solid matrices

using water is possible using apparatus designed for supercritical fluid extraction (Figure 11A). By placing the soil sample in the extraction cell of the SFE apparatus, effective extraction using water can be accomplished at elevated temperature ($> 200^\circ\text{C}$) and pressure (50 atm). Quantitation is then achieved using SPME by inserting the fibre in the water extract (Figure 11B) followed by chromatographic analysis.

Preliminary results using this type of approach are shown in Table 6.

Headspace-SPME

Instead of using SPME to extract from the aqueous extract or slurried sample an alternative strategy uses headspace-SPME. In this approach SPME is used to extract volatile or semi-volatile analytes from the headspace above a solid sample. A soil sample (10 mg to 1 g) is placed in a headspace vial and the vial is

Figure 10 SPME-GC-MS chromatogram of a real soil sample contaminated with chlorophenols. (*Journal of Chromatography A*, 806: 317, 1998, Copyright Elsevier Science.) GC conditions: column, 30 m length \times 0.25 mm internal diameter \times 0.5 μm film DB-5.625 fused silica; injection, splitless mode with an injector temperature of 290°C , and a splitless time of 1 min; temperature programme $60\text{--}190^\circ\text{C}$ at $30^\circ\text{C min}^{-1}$ and from 190 to 310°C at $10^\circ\text{C min}^{-1}$. Slurry preparation: 40 mg of sieved soil (mesh size 1.981 mm and 2.000 mm) was prepared in 12.5 mL, of $20 \mu\text{g mL}^{-1}$ internal standard solution and, then, the solution was diluted to 50 mL with pH 1 buffer solution and 5 M KCl added. SPME conditions: 85 μm polyacrylate coated fibre; adsorption time, 40 min with stirring at 1000 rpm; desorption time, 2 min at 290°C . Peak identification: 2,4-DCP = 2,4-dichlorophenol; 2,4,6-TCP = 2,4,6-trichlorophenol; 2,3,4,6-TeCP = 2,3,4,6-tetrachlorophenol; IS = 2,4,6-tribromophenol; PCP = pentachlorophenol.

sealed by crimping with an appropriate cap, e.g. an open-centred aluminium cap containing a PTFE/grey-butyl moulded septum. In order to promote the release of volatiles a small quantity of water (10–30%) may be added to the soil sample. In addition, the volatility of an analyte can be increased by heating the sample. This can simply be done by placing the sealed sample vial in a thermostatically-controlled water bath. It has been suggested that at ambient temperature this headspace SPME approach can be effective for three ring PAH compounds or more volatile compounds.

Conclusion

While SPME has been applied to a wide range of application areas, it is those with an environmental theme that have been mainly used to date. The main focus of this article is on the method of operation for a range of sample types. Specific examples have been provided as to the application of SPME for extraction of analytes from aqueous and solid

matrices. In addition, the different forms of analysis from aqueous samples are considered, i.e. direct and headspace sampling while for solid samples, the use of a slurry technique, prior to hot water extraction and headspace SPME is considered. The experimental data provided should act only as a guide to the potential and diverse applications of SPME.

Introduction

In modern chemical analysis various physicochemical methods are used to achieve high detection sensitivity. In trace analysis, reported detection levels are often measured in $\mu\text{g mL}^{-1}$ (ppm) ng mL^{-1} (ppb), as well as in pg mL^{-1} (ppt). Achievement of such low detection levels has been made possible by the use of modern analytical instruments equipped with new types of detectors and by improved sample prepara-

tion methods. Both factors are closely related to the purity of the solvents used as the mobile phases in different variants of liquid chromatography (LC), capillary zone electrophoresis (CZE), liquid-liquid (LLE) and solid-phase (SPE) extraction, filtration and flotation. Moreover, high-purity solvents are also employed to dilute samples investigated using chromatography, spectral and electrochemical analysis. Thus, solvents used in chemical analysis must fulfil many physicochemical requirements.

High-purity solvents, for example for liquid chromatography (LC) and/or for spectroscopy, are produced by many manufacturers. However, purification and quality testing of solvents are often necessary before use, particularly in the above-mentioned techniques

applicable to multicomponent systems. For instance, the mobile phases in LC, CZE and SPE are often modified by different organic and/or inorganic salts.

In this article the most important physicochemical properties of commonly used solvents are briefly reviewed, including methods of their purification, recovery and quality testing.

Solvents: Properties and their Usage

In many cases the purity of the solvents used has a great influence on whether the molecular processes occurring in a multicomponent system proceed in the desired manner. The quality of measured data can often be improved by using high-purity solvents. For chromatography or spectroscopy a good solvent is characterized by high purity, and in consequence, by low values characterizing the transparency (cut-off) and refraction (refractive index). Parameters such as reactivity and good miscibility are also important criteria for solvent selection. In LC investigations, multicomponent solvents which have low boiling points (between 20 and 60°C) and low viscosity ($\eta < 50$ cP) are preferred. A good solvent should be able to dissolve the sample, although this is seldom a problem in analytical separations when the mobile phase has the correct strength.

The important physical parameters characterizing the most commonly used solvents in many analytical techniques are listed in Table 1. On the basis of this table it can be seen that LC is the most frequently applied technique and consequently it consumes a large amount of the various solvents. A high usage of solvents in LC results from the various separation modes of this technique.

In normal-phase (adsorption) liquid chromatography (NPLC) aliphatic hydrocarbons (e.g. *n*-hexane, *n*-heptane) are usually used as the mobile phase. The elution strength of these solvents is often modified by other organic compounds. A fundamental problem with NPLC eluents is the presence of dissolved water and trace amounts of the higher-fraction olefines. These contaminations can cause changes in the cut-off values (UV detection, spectrophotometry), baseline perturbation and poor reproducibility of retention data. Halogenated solvents such as dichloromethane can react with other reactive organic solvents (e.g. acetonitrile) and form crystalline products.

In reversed-phase liquid chromatography (RP-LC) aqueous solutions of methanol, acetonitrile, tetrahydrofuran and dioxane are used as eluents. In this mode of LC the most serious problem, besides the purity of the organic modifiers in the mobile phase, is the

Table 1 Properties of solvents used in various analytical techniques

purity of the water, which may contain trace impurities of phenols, hydrocarbons, etc. Tetrahydrofuran is frequently used as the solvent in gel permeation chromatography (GPC). It must be stabilized by butylate hydroxytoluene (BHT), which is used as an antioxidant. However, in ion suppression and ion pair RP-LC the mobile phases are often modified by the addition of compounds which can change the dissociation constants of analytes, such as inorganic and organic acids or ionic substances (e.g. ammonium chloride, cetyl chloride). All these components may contain inconvenient impurities which can also crystallize, causing some perturbation in detection during the elution process. As a result of these impurities extra peaks may appear in the chromatograms, making identification of the substances analysed more difficult. The impurities may interfere with the analyte's retention even if a UV-transparent mobile phase (e.g. methanol–water, acetonitrile–water and/or ethanol–water) is used.

Figure 1 shows the peak heights of different compositions of solvent gradually decreasing from their cut-off limits to become very low or almost negligible at wavelengths larger than 320 nm.

Another factor which influences the separation process and which may result from solvent impurities during chromatographic elution is peak tailing and/or peak splitting. In solid-phase extraction (SPE) irreversible sorption of solvent impurities on active sites of packing materials (e.g. surface silanols or chemically bounded ligands with polar groups such as $-OH$, $-NH_2$, $-CN$, etc.) can be manifested by relatively high differences in reproducibility of recoveries.

Therefore, before chromatographic or spectroscopic measurements are made, a special preparation

(e.g. isolation, purification and preconcentration) of the sample is recommended. For this purpose techniques such as LLE, SPE, filtration and membrane separation are used. It should be mentioned that high-purity solvents are required to prepare analytical samples.

Methods of Solvent Purification

There are many methods of solvent purification, but the most common are simple distillation, fractional distillation and steam distillation. A recent method of solvent purification using solid-state packing materials is becoming more popular. It can be carried out by LC, SPE, filtration, and ultrafiltration utilizing membranes.

Distillation

Distillation is the oldest and simplest procedure for solvent purification, and it is also inexpensive. It is based on Raoult's law, which states that the partial vapour pressure of a solvent is proportional to its mole fraction. The physical foundations of separation by distillation depend on the distribution of constituents between the liquid and the vapour phases being at equilibrium. In general, the composition of the vapour is different from the composition of the distillate. Only azeotropic mixtures distill without a change in their composition. However, during distillation of a normal mixture the principal component with the lowest boiling point distills first, followed by compounds with higher boiling points. The effectiveness of distillation depends on the physical properties of the components in the mixture, the equipment used and the method chosen.

Figure 1 Plot of peak heights versus wavelength of radiation in the UV spectrophotometer for the mobile phase methanol (analytical grade) – water (home purified) at compositions 30 : 70% (v/v) (○), 50 : 50% (v/v) (●) and 70 : 30% (v/v) (▲), and composition 50 : 50% (v/v) (□) prepared from LC-grade solvents (J. T. Baker, Deventer, The Netherlands). (Reproduced with permission from Buszewski, Bleha and Berek (1985).)

Simple distillation Simple distillation refers to the process in which molecules transferred from the liquid phase to the vapour phase are not subjected to partial condensation or contact with the condensed liquid prior to reaching the condenser. The composition of the vapour near the liquid phase does not change as it moves toward the condenser. In this technique, equipment requirements are minimal; usually a flask fitted with a condenser and a product receiver are sufficient.

Fractional distillation Fractional distillation is used when a more efficient separation process than simple distillation is required. This type of distillation is an equilibrium process in which the composition of the distillate is constantly changing as the distillation proceeds. The main element of the apparatus is the distillation column, which consists of a series of

plates placed one above the other in a suitable tube. The column is placed under the receiver. Liquid evaporating from one (lower) plate condenses on the next (higher) plate, where it again evaporates. On each plate an equilibrium between the liquid and the vapour is established. Vapour enriched in more volatile components flows upwards, whereas vapour enriched in less volatile components flows downwards. The performance of the column increases with an increasing number of plates.

Steam distillation Steam distillation is a simple distillation procedure in which evaporation of the mixture is achieved either by continuously blowing steam through the mixture or by boiling water and the sample together. If the sample contains both hydrophobic and hydrophilic components, two layers of distillate develop. In typical steam distillation two layers can be recovered individually. Aqueous distillation seems to provide the best compromise between time, cost and effort.

In many cases satisfactory results are achieved by using distillation for solvent purification. Water used in LC investigations should normally not be purchased, but should be prepared by the user. An inexpensive and easy laboratory procedure for water purification is as follows: deionized water with added alkaline solution of KMnO_4 is left for a few days, and then the solution is distilled twice in an apparatus made of hard glass. The conductivity of water purified in this fashion is 10^{-6} S m^{-1} .

In Figure 2, plots of absorbance for three combinations of water and methanol mixtures of various purities are shown. The main source of UV absorption by the binary mobile phase was evidently impurities in the methanol. A comparison of the two bottom curves shown in Figure 2 proves the effectiveness of water purification by distillation.

Other solvents, such as aliphatic and aromatic hydrocarbons, alcohols, ethers, tetrahydrofuran and halogenated solvents, can also be purified using distillation methods. However, in many cases the solvent impurities, e.g. water in aliphatic hydrocarbons or halogenated solvents, can make distillation less efficient. In these cases it is necessary to use more effective methods for solvent purification.

Adsorption Methods

In adsorption chromatography (NPLC), control of the water content in the solvents is important. In some cases it is preferred to mix known amounts of dry and water-saturated solvents together in order to know the percentage of water saturation. Generally, analytical grade purity solvents should not contain

Figure 2 Plot of absorbance for mixtures of water and methanol at 254 nm versus the composition of the solution obtained on the basis of spectrophotometric data using a 3 cm quartz cuvette. Key: ∇ , methanol (analytical grade) and water (home purified); \bullet , methanol (LC grade, J. T. Baker, Deventer, The Netherlands) and water (home purified); and \circ , water and methanol (LC grade, J. T. Baker). (Reproduced with permission from Buszewski, Bleha and Berek (1985).)

impurities. On the other hand, the addition of activated molecular sieve beads (0.4 or 0.5 nm in diameter) to the flask with the solvents clearly improves their purity and reduces the water content. Various impurities, in addition to water, can be often removed by adsorption methods, particularly frontal analysis, which is often utilized in LC.

In this method a glass column packed with small adsorbant particles (0.15–0.2 mm in diameter), usually dried silica gel or alumina oxide, is used (Figure 3). Before solvent purification the column is heated at 473 K for 8 h under vacuum conditions (10^{-3} Torr) to remove physically adsorbed water. After this operation, unpurified solvent is injected into the column using a syphon-type injector. The purified solvent is collected in a solvent receiver equipped with a moisture trap.

During LC investigations purification and stabilization of the mobile phase is frequently carried out on precolumns. These columns are located between the solvent reservoir and the injector valve. SPE, in conjunction with frontal analysis, is also used for solvent clear-up. It is mainly used for purifying small amounts of solvents, particularly for sample dilution.

Filtration and Membrane Techniques

A reliable and easy laboratory technique for solvent purification is filtration. The mobile phase containing added buffers or reagents may be filtered through a filter (0.5 μm mesh or smaller) to remove particulate matter which can damage the system. The equipment for filtration is very simple, generally consisting of an Erlenmeyer flask connected to vacuum and

Figure 3 Apparatus for solvent purification. 1, glass column with cooling jacket; 2, glass sinter; 3, silica gel or alumina adsorbent; 4, syphon-type injector; 5, container for unpurified solvent; 6, PTFE tube; 7, moisture trap; 8, valve; 9, receiver for purified solvent. (Reproduced with permission from Buszewski, Lodkowski and Trocewicz (1987).)

a reservoir, in which a porous filter disc or membrane is placed. The porous discs are usually made from nonporous spherical glass beads (1–2 μm in diameter) and/or PTFE. Membranes are usually made from PTFE, cellulose or nylon. To improve the efficiency of the separation process, the surface of the filter discs or membrane is often modified chemically, as are the packing materials, with chemically bonded phases in RP-LC and/or SPE. In this case the surface properties

(hydrophobic or hydrophilic) of filters and/or membranes determine the degree of purification.

Water may be purified satisfactorily using a compact water purification system that combines filtration, deionization and charcoal treatment in a convenient, high-volume unit.

Ultrafiltration Ultrafiltration is the other alternative to filtration, where large molecules are separated from solution by using membranes. Membranes are commercially available for separation molecules with relative molecular masses in the range 10^3 – 10^6 . Ultrafiltration is primarily used for the isolation of low- or high-molecular mass substances from different solvents. **Figure 4** shows a comparison of the efficiency of acetonitrile purification utilizing frontal analysis combined with ultrafiltration.

Reverse osmosis Reverse osmosis is similar to ultrafiltration except that membranes of a much smaller pore diameter are employed and the operating pressure is much higher. The operating pressure must exceed the natural osmotic pressure. This technique has been successfully applied to the purification of water and organic solvents.

Dialysis In dialysis, solvents are purified by differential diffusion through membranes under a concentration gradient. The overall efficiency of this process is controlled by the ratio of the flow rates and the properties of membrane, fluid channel and local fluid velocity.

Recovery and Quality Control

After the purification process or before using solvents in various analytical techniques, quality control is necessary. For this reason, many different analytical

methods have been utilized for measuring the characteristic parameters. Generally, chromatographic techniques such as gas chromatography (GC), LC, thin-layer chromatography (TLC) have been used, but ultraviolet (UV), infra-red (IR) and nuclear magnetic resonance (NMR) spectroscopy can also be applied. Water in many organic solvents is usually determined by Karl Fischer titration. On the basis of experimental data obtained before and after purification the efficiency of the clean-up procedure is determined. In general, the efficiency of purification process, e.g. the recovery, is expressed by the coefficient R . This parameter is defined as the ratio of the volume or concentration of removed impurities to the volume or concentration of solvent before purification:

$$R \pm \sigma = (V_a \pm \sigma_a)(V_b \pm \sigma_b) \times 100\% \text{ (v/v)} \quad [1]$$

or:

$$R \pm \sigma = (C_a \pm \sigma_a)(C_b \pm \sigma_b) \times 100\% \text{ (v/v)} \quad [2]$$

where V_a , C_a and V_b , C_b denote volume or concentration of the removed impurities and solvent samples, respectively, and σ , σ_a , σ_b are individual standard deviations.

Table 2 summarizes the results of solvent purification by frontal analysis. In each case, purification of the solvent improves its absorbance at the cut-off point (ΔA).

The small improvement found in the case of the LC grade methanol B is as expected for this high-purity solvent. The high impurity (absorbance difference, $\Delta A = 77.5\%$) of analytical grade methanol A precludes its use in LC investigations. Similarly, toluene, benzene, tetrahydrofuran and acetonitrile A cannot be used in LC measurements without prior purification.

Recovery values for the purification of water, acetonitrile, alcohols, ketones, aliphatic and aromatic hydrocarbons obtained in distillation methods are usually in the range 85–95% (v/v). In the case of halogenated solvents this range is narrower, i.e. 75–80% (v/v). Utilizing membrane techniques for solvent clear-up, it is possible to obtain recovery in the range 90–97% (v/v).

SORBENT SELECTION FOR SOLID-PHASE EXTRACTION

E. M. Thurman, US Geological Survey, Lawrence, KS, USA

Copyright © 2000 Academic Press

Solid-phase extraction (SPE) is a method of sample preparation that concentrates and purifies analytes from solution by sorption onto a disposable solid-phase cartridge, followed by elution of the analyte

with a solvent appropriate for instrumental analysis. The mechanisms of retention include reversed phase, normal phase, size exclusion, and ion exchange. Solid-phase extraction was invented in the mid 1970s as an alternative approach to liquid-liquid extraction for sample preparation.

Initially, SPE was based on the use of polymeric sorbents, such as XAD resins, which were packed in small disposable columns for use on drug analysis. The early environmental applications consisted of both XAD resins and bonded-phase sorbents, such as C₁₈. These precolumns were used for sample trace enrichment prior to liquid chromatography and were often done on line, which means at the same time as liquid chromatography. However, these first, steel, on-line precolumns were quickly replaced with an off-line column made of plastic, in order to be both inexpensive and disposable. Eventually, the term solid-phase extraction was coined for these low-pressure extraction columns.

SPE columns are now typically constructed of polypropylene or polyethylene and filled with 40- μ m packing material with different functional groups. A 20- μ m polypropylene frit is used to contain from 50 mg to 10 g of packing material. A liquid sample is passed through the column and analytes are concentrated and purified. The sample volume that can be applied ranges from 1 mL to over 1 L. The sample may be applied to the column by positive pressure or by vacuum manifold. After quantitative sorption of the analyte, it is removed with an appropriate elution solvent.

Therefore, SPE is a form of 'digital' liquid chromatography that removes the solute onto a solid-phase sorbent by various sorption mechanisms. The term 'digital' refers to the on/off mechanism of sorption and desorption. The goal of SPE is to quantitatively remove the analyte from solution and completely recover it in an appropriate solvent. Purification consists of removing the analyte from interfering compounds and concentrating the analyte in a small volume of solvent. For example, pesticides are concentrated from a water sample by SPE into a small volume of organic solvent for analysis by gas chromatography/mass spectrometry. Interfering substances, such as humic and fulvic acids, ionic metabolites and salts are removed.

Typically, SPE replaces liquid-liquid extraction as a sample preparation tool and provides a method that is simple and safe to use. The benefits of SPE include: high recoveries of analytes; purified extracts; ease of automation; compatibility with chromatographic analysis; and reduction in the consumption of organic solvents. As a result of the flexibility that SPE offers, it has found application in the preparation of environ-

mental, clinical, and pharmaceutical samples. The simplicity of the SPE procedure and the use of disposable SPE supplies have encouraged the design of automated sample preparation stations, which decrease the time and cost of sample preparation. Finally, recent advances in on-line methods of SPE allow automation of sample preparation directly to both liquid and gas chromatography.

How to do SPE

Figure 1 illustrates the four-step process of SPE. First the solid-phase sorbent is conditioned (step 1). This simply means that a solvent is passed through the sorbent to wet the packing material and to solvate the functional groups of the sorbent. Furthermore, the air that is present in the column is removed and the void spaces are filled with solvent. Typically, the conditioning solvent is methanol, which is then followed with water or an aqueous buffer. The methanol followed by water or buffer activates the column in order for the sorption mechanism to work properly for aqueous samples. Care must be taken not to allow the bonded-silica packing or the polymeric sorbent to go dry. In fact, if the sorbent dries for more than several minutes under vacuum, the sorbent *must* be reconditioned. If it is not reconditioned the mechanism of sorption will not work effectively and recoveries will be poor for the analyte.

Another cleaning step of the sorbent may also be added during conditioning, if necessary. Simply, the eluting solvent is passed through the column after the methanol wetting step to remove any impurities that may be present in the packing material. This cleaning step would then be followed by methanol and aqueous buffer, which prepares the column for sample addition.

Next, the sample and analyte are applied to the column (step 2, Figure 1). This is the retention or loading step. Depending on the type of sample, from 1 mL to 1 L of sample may be applied to the column either by gravity feed, pumping, aspirated by vacuum, or by an automated system. It is important that the mechanism of retention holds the analyte on the column while the sample is added. The mechanisms of retention include Van der Waals (also called non-polar, hydrophobic, partitioning, or reversed-phase) interaction, hydrogen bonding, dipole-dipole forces, size exclusion, and cation and anion exchange. During this retention step, the analyte is concentrated on the sorbent. Some of the matrix components may also be retained and others may pass through, which gives some purification of the analyte.

Step 3 (Figure 1) is to rinse the column of interferences and to retain the analyte. This rinse will

Figure 1 The four-step process of solid-phase extraction. Step 1, condition sorbent; step 2, apply sample and analyte; step 3, wash; step 4, analyte elution. (Reprinted from Thurman and Mills (1998) Copyright John Wiley & Sons, Inc.)

remove the sample matrix from the interstitial spaces of the column, while retaining the analyte. If the sample matrix is aqueous, an aqueous buffer or a water/organic-solvent mixture may be used. If the sample is dissolved in an organic solvent, the rinse solvent could be the same solvent.

Finally, in step 4 an appropriate solvent is used that is specifically chosen to disrupt the analyte-sorbent interaction, resulting in elution of the analyte from the sorbent. The eluting solvent should remove as little as possible of the other substances sorbed on the column. This is the basic method of solid-phase extraction.

Columns and Apparatus for SPE

The sorbents used for SPE are packaged in three basic formats. There are discs, cartridges, and syringe barrels. **Figure 2** shows the different types of presentation of SPE products. The discs are available in different diameters from 4 to 90 mm, the 'standard' disc size being 47 mm. Cartridges vary from as little as 100 mg to 1 g or more. Syringe barrels are available in different volumes and with different masses of packing material. Syringe barrels range in size from 1 to 25 mL and packing weights from 50 mg to 10 g. These various sorbents allow for the effective treat-

Figure 2 The three formats of SPE: (A) discs; (B) cartridges; and (C) syringe barrels. (Reprinted from Thurman and Mills (1998) Copyright John Wiley & Sons, Inc.)

ment of different types of sample and different sample volumes.

Currently, the most commonly used format for SPE consists of a syringe barrel that contains 40- μm sorbent material, with a 20- μm polypropylene frit at the bottom and a 20- μm polypropylene frit at the top of the syringe. The syringe barrel is typically polypropylene with a male Luer-tip fitting and is disposable. Some vendors do make glass syringe barrels and Teflon frits, but these configurations are used less frequently. The glass and Teflon system is used when one is interested in the analysis of plasticizers or is concerned with the potential sorption of specific analytes onto the polyethylene tube.

Solvent reservoirs may be used to increase the volume of the syringe barrel. Reservoirs are typically 50–100 mL in volume. Coupling fittings are used to join the reservoirs and syringe barrels between the Luer fitting and the opening of the syringe barrel (Figure 3).

The barrel of the syringe terminates in a male Luer tip. The male Luer tip is the standard fitting on SPE cartridges, so that they are interchangeable with different SPE vacuum manifolds. The vacuum manifold is used to draw the sample and eluting solvents through the syringe barrel under negative pressure by applying a vacuum to the manifold. Figure 4A shows a typical vacuum-manifold system, which is fitted with a small vacuum pump and a waste receiver. Stopcock valves are available to control the vacuum applied to each column. Other types of sample processing that may be used include centrifugation (Figure 4C) and positive pressure (Figure 4D), which forces the sample through the syringe barrel from above. Simple gravity flow through the syringe barrel or cartridge may also be used (Figure 4B).

A typical solid-phase extraction cartridge (see Figure 2) consists of a polyethylene body with both a female and male Luer tip for positive pressure from a syringe, or negative pressure from a vacuum manifold. Polyethylene frits measuring 20 μm are placed at either end of the cartridge to hold the packing material in place. The packing material is packed and compressed to improve or optimize flow characteristics.

The third type of SPE format is the disc, which is available in several styles by different manufacturers. One of the most popular extraction discs is the Empore® extraction disc, which consists of 8–12 μm particles of packing material embedded in an inert matrix of polytetrafluoroethylene (PTFE) fibrils. Because the particles are suspended in PTFE, no binder is required to give structure to the disc and the matrix is essentially inert. The discs are not coated with PTFE so that they can interact with the solvent and sample during extraction. The discs are available in

Figure 3 Disposable column and reservoir. (Reprinted from Thurman and Mills (1998) Copyright John Wiley & Sons, Inc.)

a membrane format as loose discs, or are placed in a syringe-barrel format called an extraction disc cartridge. The syringe-barrel format consists of a standard polyethylene syringe that is fitted with a 20- μm Teflon frit, an Empore® disc, and a prefilter of glass fibre. This arrangement allows for micro-scale work using the disc. Discs are conditioned and used in

Figure 4 Techniques for processing SPE cartridges: (A) vacuum manifold; (B) gravity; (C) centrifugation; and (D) positive pressure. (Reprinted from Thurman and Mills (1998) Copyright John Wiley & Sons, Inc.)

a similar fashion to the packed columns, with flow of sample by negative pressure by vacuum.

A major advantage of the disc format is rapid mass transfer because of the greater surface area of the 8–12 μm particles, which results in high flow rates for large volume samples. This rapid flow rate is especially useful for environmental samples where 1 L of water may be processed in as little as 15 min. Rapid mass transfer owing to embedding of small particles into the disc also means that channelling is reduced and small volumes of conditioning and elution solvents may be used. For example, a 4-mm disc in syringe format (extraction disk cartridge) requires

only 100 μL of elution solvent, and a 7-mm disc uses only 250 μL . This volume is small compared with the millilitre amounts applied to a 3–5-mL syringe barrel that contains loose packing.

Another type of disc called SPEC[®] manufactured by Ansys, Inc., uses a glass-fibre matrix rather than Teflon to hold the sorbent particles. This disc has a somewhat more rapid flow rate and is more rigid and thicker than the Teflon disc. There is another disc called the Speedisk[®] manufactured by J. T. Baker, which consists of 10- μm packing material that is sandwiched between two glass-fibre filters without any type of Teflon binder.

Sorbents and Modes of Interaction

The sorbents used for SPE are similar to those used in liquid chromatography, including normal phase, reversed phase, size exclusion, and ion exchange. Normal-phase sorbents consist of a stationary phase that is more polar than the solvent or sample matrix that is applied to the SPE sorbent. This means that water is not usually a solvent in normal-phase SPE because it is too polar. Normal-phase sorbents, therefore, are used in SPE when the sample is an organic solvent containing an analyte of interest. Polar interactions, such as hydrogen bonding and dipole–dipole interactions, are the primary mechanisms for solute retention.

Reversed-phase sorbents are packing materials that are more hydrophobic than the sample. Reversed-phase sorbents are commonly used in SPE when aqueous samples are involved. The mechanism of interaction is Van der Waals forces (also called non-polar, hydrophobic, or reversed-phase interactions) and occasionally secondary interactions such as hydrogen bonding and dipole–dipole interactions. Size-exclusion sorbents utilize a separation mechanism based on the molecular size of the analyte. It is a method only recently being used in SPE, usually in conjunction with reversed phase or ion exchange. Ion-exchange sorbents isolate analytes based on the ionic state of the molecule, either cationic or anionic,

where the charged analyte exchanges for another charged analyte that is already sorbed to the ion-exchange resin. SPE applications in this case are essentially identical to classical ion exchange.

Thus, the mechanisms of interaction include: hydrogen bonding and dipole–dipole forces (polar interactions); Van der Waals forces (non-polar or hydrophobic interactions); size exclusion; and cation and anion exchange. Some sorbents combine several interactions for greater selectivity. The extensive line of sorbent chemical structures facilitates one of the most powerful aspects of SPE, which is selectivity. Selectivity is the degree to which an extraction technique can separate the analyte from interferences in the original sample. The number of possible interactions between the analyte and the solid phase facilitates this selectivity.

Table 1 lists the common sorbents that are available for SPE and their mode of action (i.e. reversed phase, normal phase, ion exchange, and size exclusion). Typically the sorbents consist of 40- μm silica gel with approximately 60- \AA -pore diameters. Chemically bonded to the silica gel are the phases for each mode of action. For reversed-phase sorbents, an octadecyl (C_{18}), octyl (C_8), ethyl (C_2), cyclohexyl, and phenyl functional groups are bonded to the silica. Typical loading of reversed-phase sorbents varies from approximately 5% for the C_2 phase to as much as 17% for the C_{18} phase. The per cent loading is the

Quaternary amine	$-(\text{CH}_2)_3\text{N}^+(\text{CH}_3)_3$	0.7 meq g^{-1}
Carboxylic acid	$-(\text{CH}_2)_2\text{COOH}$	0.4 meq g^{-1}
Aromatic sulfonic acid	$-(\text{CH}_2)_3\text{-phenyl-SO}_3\text{H}$	1.0 meq g^{-1}
Size exclusion		
Wide-pore hydrophobic (butyl)	$-(\text{CH}_2)_3\text{CH}_3$	5.9% C
Wide-pore ion exchangers—COOH		12.2% C

amount of C_2 or C_{18} phase that is present by weight of carbon. The capacity of the sorbent in mg g^{-1} of analyte that may be sorbed is related to both the chemistry of the phase and the loading weight of carbon. Polymeric sorbents, such as styrene divinylbenzene and carbon, also are used for reversed-phase SPE. These sorbents were some of the classical reversed-phase sorbents introduced in the 1960s. They are currently produced in purified form and are useful for the isolation of more polar solutes that have low capacities on the C_{18} reversed-phase sorbents.

For normal-phase SPE, cyanopropyl (CN), aminopropyl (NH_2), and diol functional groups are chemically bonded to the silica gel. The loading on the cyano, amino, and diol columns are sufficiently large (~ 6 – 10% as carbon) in that they may sometimes be used for reversed-phase applications, especially for the removal of hydrophobic solutes from water or other polar solvents. These hydrophobic solutes would otherwise sorb too strongly to a more hydrophobic C_8 or C_{18} sorbent and would be difficult to elute. Straight silica gel is also used for normal-phase SPE along with Florisil (magnesium silicate) and alumina (aluminum oxide in neutral, basic, and acidic forms).

Ion-exchange sorbents usually contain both weak and strong cation and anion functional groups bonded to the silica gel (Table 1). Strong cation-exchange sorbents contain ion-exchange sites consisting of sulfonic acid groups, and weak cation-exchange sorbents contain sites consisting of carboxylic acid groups. Strong anion-exchange sites are quaternary amines, and weak anion-exchange sites are primary, secondary, and tertiary amines. Strong and weak refers to the fact that strong sites are always present as ion-exchange sites at any pH, while weak sites are only ion-exchange sites at pH values greater or less than the pK_a , which determines whether a site contains a proton or not. The typical loading for an ion-exchange sorbent is expressed in meq g^{-1} of sorbent, which is called the exchange capacity of the sorbent. The values vary from $\sim 0.5 \text{ meq g}^{-1}$ to 1.5 meq g^{-1} . These exchange capacities are somewhat less than a typical ion-exchange resin, which will have from 2 to 5 meq g^{-1} because of a higher density of ion-exchange sites. Also these SPE ion-exchange sorbents are not as rugged as the polymeric ion-exchange resins because of the silica matrix of the SPE sorbent, which is susceptible to dissolution by strong acid or base. The typical ion-exchange resin, however, consists of a cross-linked styrene-divinylbenzene polymer.

Size-exclusion sorbents, called wide-pore sorbents (Table 1), use a silica-gel matrix with a large pore size (approximately 275 – 300 \AA) rather than the 60-\AA

pores of most bonded-phase silicas. The advantage of the larger pore size is that molecules of larger molecular weight (> 2000 daltons) may enter the pore of the sorbent and sorb by hydrophobic, polar, or ion exchange interactions. Two examples are shown in Table 1. One is a hydrophobic sorbent of C_4 (butyl) with a carbon loading of almost 6% , and the other is a weak cation sorbent using the carboxyl exchange site.

Another packing material, which is not listed in Table 1, was recently introduced for drug analysis. It is a mixed-mode resin. This packing material contains both a bonded reversed-phase group (typically a C_8) and a cation-exchange group on a silica gel or a polymeric matrix. The combination of bonded groups is used so that both types of mechanisms retain the analyte at different times, or simultaneously, in the clean up of complex samples of urine and blood. The principle of the mixed-mode resin is that different wash solvents may be used to remove interferences, but that the solute is always retained by one or both of the interactions.

Applications of SPE

Table 2 shows a general application guide for the use of SPE sorbents. The C_{18} reversed-phase sorbent has historically been the most popular packing material and has been used most frequently. The surface of the sorbent is one of the most hydrophobic and has a large capacity. Capacity is the amount of analyte sorbed (usually expressed in mg g^{-1}) before breakthrough occurs. Applications of C_{18} reversed phase include: isolation of hydrophobic species from aqueous solutions, such as drugs and metabolites from urine, serum, plasma, and other biological fluids; desalting of peptides and oligonucleotides; isolation of pigments from wine and beverages; and trace enrichment of pesticides from water for analysis by gas chromatography/mass spectrometry or high pressure liquid chromatography.

Graphitized carbon and reversed-phase polymeric sorbents are also frequently used in environmental applications, such as trace enrichment, for soluble molecules that are not isolated by reversed-phase sorbents, such as C_{18} . Water soluble analytes require a more hydrophobic sorbent with greater surface area per gram for complete retention. Carbon and polymeric sorbents may also be used for polar metabolites of drugs and pharmaceuticals that are poorly retained on C_{18} . Another advantage of the aromatic sorbents is their selective interaction with the aromatic rings of analytes. Because both the graphitized carbon and the styrene divinylbenzene structures contain aromatic rings, they have the ability to sorb analytes by a

Table 2 Selected application guide for SPE

<i>Sorbent</i>	<i>Application</i>
C ₁₈	Reversed phase application one of the most hydrophobic phases Drugs in serum, plasma, and urine Organic acids in wine Pesticides in water by trace enrichment
Graphitized carbon polymeric sorbents (styrene divinylbenzene)	Reversed phase application one of the most hydrophobic phases Trace enrichment of polar pesticides from water Isolation of polar drug metabolites
C ₈	Reversed phase application—hydrophobic phase Drugs from serum, urine, and plasma Peptides in serum and plasma
Silica	Normal phase application—polar neutral phase Isolation of low to moderate polarity species from non-aqueous solution Lipid classification
Florisil	Normal phase application—polar slightly basic phase Isolation of low to moderate polarity species from non-aqueous solution Pesticides in food and feeds Polychlorinated biphenyls in transformer oil
Alumina A	Normal phase application—acidic polar phase Isolation of hydrophilic species in non-aqueous solution Low capacity cation exchange
Cation exchange	Cation exchange phase Isolation of cationic analytes in aqueous or non-aqueous solutions Fractionation of weakly basic proteins and enzymes
Anion exchange	Anion exchange phase Isolation of anionic analytes in aqueous or non-aqueous solutions Extraction of acidic and weakly acidic proteins and enzymes
Mixed mode	Reverse phase (C ₈) and cation exchange phase Isolation of basic and amphoteric drugs from serum, plasma, and urine
Aminopropyl NH ₂	Normal phase, reverse phase, and weak cation exchange Low capacity weak anion exchanger Drugs and metabolites from body fluids Petroleum and oil fractionation
Cyanopropyl CN	Normal phase and reversed phase Analytes in aqueous or organic solvents Drugs and metabolites in physiological fluids
Diol OH	Normal phase and reversed phase Analytes in aqueous or organic solvents Drugs and metabolites in physiological fluids

specific pi-pi interaction. This sorption mechanism may selectively isolate aromatic compounds.

The C₈ reversed-phase sorbents (Table 2) are often the most popular sorbent for drug analysis because of a shorter hydrocarbon chain than a C₁₈ sorbent. The shorter chain length makes it much more easy for secondary interactions between the analyte and the silica gel which enhances retention of the analyte. This added interaction is useful in the purification of drugs and metabolites from blood and urine because

they contain basic nitrogen atoms that may hydrogen bond to the silica gel.

Normal-phase sorbents such as silica and Florisil are used to isolate low to moderate polarity species from non-aqueous solutions. Examples of applications include lipid classification, plant-pigment separations, and separations of fat-soluble vitamins from lipid extracts, as well as the clean up of organic solvent concentrates obtained from a previous SPE method or liquid-liquid extraction. Alumina is

used to remove polar species from non-aqueous solutions. Examples include vitamins in feeds and food, and antibiotics and other additives from feed. Normal-phase chromatography has been used for a number of years and most applications for normal-phase column chromatography may be easily transferred over to normal-phase SPE.

Cation and anion exchange is used to isolate ionic compounds from either aqueous or non-aqueous solutions. Examples of applications are: isolation of weakly basic proteins; removal of acidic pigments from wines and fruit juices; and the removal of organic acids from water. Many of the applications of classical ion exchange may be used in ion-exchange SPE; however, care must be exercised in the use of strong acids and bases with SPE ion-exchange sorbents that are based on a silica matrix. Furthermore, care must be taken not to exceed the ion-exchange capacity of the sorbent.

Finally, sorbents such as aminopropyl, cyanopropyl, and diol can be used for both reversed-phase and normal-phase separations. Many manufacturers supply their sorbents in variety packs, which may be used for methods development. Also quality assurance reports are commonly available for the various sorbents, which is a good indication of their reproducibility.

Automation of SPE

Automation of a manual SPE method can provide many benefits, which include safety, improved results, and cost savings. Because automated workstations are mechanical they can operate in environments that are hostile, for example, noisy production locations or a refrigerated room. The use of automation results in improved precision because of reduced operator errors compared with manual methods of SPE. For these reasons automation provides for better utilization of resources.

There are many types of automation equipment for SPE. They include semi-automated instruments, workstations that carry out the entire SPE operation without intervention, and robotic systems that carry out many activities besides SPE and are specially customized for the user. Finally, there are on-line SPE-HPLC systems that allow the user to merely add the sample to the autosampler and analyse the sample directly. The concept of on-line SPE is that a sample is pumped and processed onto the SPE cartridge while the liquid chromatograph or gas chromatograph is processing the preceding sample.

The development in the past 40 years of space exploration has brought important information about the formation and evolution of the solar system and has opened a broad study of organic matter and its continuous chemical evolution which led to the appearance of life.

The study of the physics and chemistry of planetary environments (Table 1) has provided important information about the origin of Earth's early atmosphere and comparative planetology gives a better understanding of our own planet. Titan, the largest satellite of Saturn, because of the composition and density of its atmosphere, is of particular interest for the understanding of the prebiotic chemistry on primitive Earth. Comets are also of interest since they contain very large amounts of organic material and they are considered as the most primitive objects in the solar system, retaining traces of its early evolution.

Since the beginning of space exploration, most of the many probes which have been sent to explore other planetary atmospheres and surfaces have carried analytical instruments to determine the elemental, isotopic and molecular (inorganic and organic) compositions of extraterrestrial environments. Severe constraints are required in space instrumentation such as low weight and small size, low power consumption, high mechanical strength and resistance to deep space conditions. Gas chromatography (GC) fulfils these requirements and is one of the most frequently used technique for *in situ* analysis in space missions.

Chemical sensors based on GC and mass spectrometry (MS) instrumentation have already been used in atmospheric probes or surface landings for analysing extraterrestrial environments, including the analysis of surface materials from Venus and Mars. Until recently, the equipment was only packed column GC with mainly magnetic, then quadrupole mass spectrometers (MS).

Since the Titan atmospheric probe of the Cassini-Huygens mission, launched in 1997 to reach the vicinity of Saturn in 2004, highly sensitive pyrolysis-GC-MS instruments have been developed using capillary columns.

The Rosetta comet exploratory mission, to be launched in 2003, will use, in two GC-based experiments, miniature thermal conductivity detectors (TCDs) and

a new design of time of flight mass spectrometer (TOF), based on a specific geometry of the MS allowing analysis of low mass compounds and good resolution.

This article reviews the different chromatographic instruments used in previous missions to Mars, Venus and Titan as well as those which are being developed, in particular for the forthcoming cometary mission.

Missions to Mars

Mars is presently the most likely planet on which there is a possibility of finding past, or even present extraterrestrial life. The average atmospheric pressure on its surface is extremely low, about 7 mbar. The primary atmospheric constituent, CO₂, produces a small warming of the surface above radiation temperature (Table 1).

One of the main objectives of the Viking mission to Mars was the search for Martian life. The US National Aeronautics Space Administration (NASA) sent two identical spacecraft to Mars in 1976. Each Viking lander, carrying scientific instruments, was successfully placed on the surface of Mars. Biemann was responsible for the MS instrument designed mainly for the detection of organic compounds in the GC-MS mode, but also used to determine independently the composition of the minor constituents of the lower atmosphere. In addition, biological investigations were carried out on board the landers. Oyama and Berdahl used GC in a gas exchange experiment (GEX) to determine the gas composition changes above a soil sample humidified or incubated in the presence of an aqueous nutrient.

Viking GC-MS Experiments

The GC-MS system (Table 2) was designed to analyse the organic compounds released from a heated surface sample. It consists of different sub-systems: (1) three sample ovens mounted in a sample holder, (2) a GC, (3) an effluent divider to protect the MS, (4) a carrier gas separator and (5) the MS itself.

Table 1 Extraterrestrial environments already analysed or planned to be analysed by gas chromatography

	Distance to sun (AU)	Surface temperature (°C)	Surface pressure (bar)	Atmosphere	
				Major constituents	Organic compounds
Venus	0.7	460	90	CO ₂ , N ₂	None
Earth	1	22	1	N ₂ , O ₂	Many
Mars	1.5	– 70 to 20	0.007	CO ₂ , N ₂	Not detected
Titan	9.6	– 180	1.5	N ₂ , CH ₄	Several hydrocarbons and nitriles
Comets	1.1–5.1	– 200	< 0.001	H ₂ O, CO, CO ₂ , H ₂ CO, CH ₃ OH	Many

Table 2 An overview of gas chromatography instruments of *in situ* planetary missions

<i>Mission</i>	<i>Launch arrival</i>	<i>Experiment sample size</i>	<i>Analytical columns</i>	<i>Temperature carrier gas</i>	<i>Detectors</i>
NASA Viking–Mars	1975/1976	GEX 0.1 cm ³ (gas)	One pair of Porapak Q (7.6 m × 1 mm)	24°C, He	1 Thermistor TCD (32°C)
		GC–MS 0.06 cm ³ (soil)	One Tenax coated with polymetaphenoxylene (2 m × 0.76 mm)	50°C (12min) + linear prog. to 200°C, H ₂	MS
NASA Pioneer–Venus–Venus	1978/1978	LGC 0.35 cm ³ (gas)	In parallel: one pair of Porapak N (15.85 m × 1.1 mm); one pair of PDVB (2.13 m × 1.1 mm)	18°C, He 62°C, He	In parallel: two thermistor TCDs
USSR Venera12–Venus	1978/1978	SIGMA GC (gas)	In series: one Polysorb (2 m) 1 molecular sieve (2.5 m); one reduced manganese	70°C, Ne	In series: three Ne ionization
USSR Vega–Venus	1984/1985	SIGMA-3 GC (gas and aerosol)	In parallel: one Porapak QS + N; one Porapak QS + N; one Porapak T	70°C, He, N ₂ , N ₂	He ionization + TCD; ECD; ECD
NASA/ESA Cassini–Huygens–Titan	1997/2004	GC–MS (gas and aerosol)	In parallel: one carbon molecular sieve (2 m × 0.75 mm); one glassy carbon WCOT (14 m × 1.8 mm); 1 CPP–DMPS WCOT (10 m × 1.8 mm)	H ₂ isothermal 30–60°C	Five MS sources (three connected to each column)
ESA Rosetta–comet P/Wirtanen	2003/2011	COSAC/GC–MS (nucleus)	In parallel: six WCOT capillaries; two PLOT capillaries	He 30–60°C	One MS, eight nano TCDs
		PTOLEMY/GC–MS (nucleus)	Two WCOT capillary; one He chemical trap; one cold trap		One MS

For both instruments on the Viking Lander-1 (VL-1) and Viking Lander-2 (VL-2), one sample oven could not operate and the analyses were limited to four samples from the Martian surface. Two were from the Chryse Planitia region (VL-1) and other two from Utopia Planitia (VL-2). For each sample, a number of analyses were performed with various GC oven temperature (50, 200, 350 or 500°C). The GC–MS operated successfully, as contaminant peaks (methyl chloride, fluorocarbon) were detected. The analysis of Martian soil samples demonstrated the absence of organic compounds above the detection limit of the GC–MS instrument (a few ppb for the more volatile organic compounds).

Viking Gas Exchange Experiments (GEX)

The biology instrument system had three different experiments integrated in the same package: the pyrolytic release, the label release and the gas exchange

(GEX) experiments. In the GEX experiments Martian soil samples were introduced, and a GC, with thermal conductivity detection (TCD), measured ppm concentrations of metabolic gases such as methane. An incubation gas (a mixture of CO₂, He and Kr) was introduced into the test cell and the biological activity was stimulated either by humidifying the soil or by adding a nutrient solution in the incubation chamber (temperature between 5 and 27°C). The changes in the composition of the incubation gas were measured periodically with a miniaturized GC.

The GC instrument (Table 2) was designed to analyse light gases such as N₂, O₂, CH₄, Kr, Ne and CO₂ at detection limits ranging from 20 to 60 ppm. Ar and CO were co-eluted on the Porapak Q column used. The composition of the Martian atmosphere was determined by GC at both landing sites (four analyses). The mean abundances were: CO₂ 96.2%, N₂ 2.3%, O₂ < 2.3% and Ar 1.5%, assuming that Ar abundance is an order of magnitude larger than for CO.

The gas changes that occurred in the incubation chamber of the GEX have raised much debate. The decrease of CO₂ just after wetting the sample material has been explained by pH changes. The significant amount of O₂ and its increase by humidifying the sample could be due to the decomposition of inorganic oxidants in the Martian soil.

Missions to Venus

Extreme temperatures (up to 460°C) and pressures (up to 90 atm) are encountered during the descent, with many reactive materials in a mainly CO₂ atmosphere (Table 1). The clouds of the lower atmosphere are composed of droplets of sulfuric acid. In a number of experiments, the very short time of descent of the probe through the Venusian atmosphere limited the time available for GC analysis.

Pioneer Venus Gas Chromatograph

The GC on board the sounder probe of the NASA Pioneer Venus mission was designed by Oyama and co-workers for the *in situ* measurement of the composition of the lower atmosphere of Venus. It is a modified version of the GC used in the Viking GEX (Table 2). The separation was performed on the two different analytical columns, each connected to a TCD. The analysis of light gases (mainly Ne and CO) was performed at 16°C, using a long column packed with Porapak N. The short column packed with a polydivinyl benzene (PDVB) porous polymer was used for separating gases from CO₂ to SO₂ at 62°C.

The Pioneer Venus probe entered the Venusian atmosphere on December 1978. During the time for the probe to reach the surface (54 min), the GC analysed three atmospheric samples at 52, 42 and 22 km altitudes. Chlorofluorocarbons were added to the third sample in order to calibrate the instrument. Table 3 gives the Venus atmospheric composition at

different altitudes from the Pioneer Venus GC measurements. The water result is consistent with the value of the vapour pressure in presence of sulfuric acid solutions.

For Ar, the lower abundance, as published in an earlier paper, was due to an incorrect identification (Ar was identified as O₂ and CO as Ar) as the assignment of the peaks was made on the basis of absolute retention times. Later, a correction accounting for flow rate variations and relying on retentions relative to those of Freon internal standards was published.

Venera 12 Gas Chromatograph

In December 1978 the *in situ* analysis of the chemical composition of the Venusian atmosphere was performed by Gelman and co-workers with a GC on board the USSR Venera 12 lander. The SIGMA instrument (Table 2) consists of three GC units arranged in series, each with a column connected to a pure neon ionization detector operating in the current-saturation mode with β -sources of different activities.

A column packed with a modified sorbent was used to separate H₂S, COS, SO₂ and H₂O, in the presence of CO₂. The low boiling point gases (O₂, N₂, Kr, CH₄ and CO) were analysed with a column packed with molecular sieves. The third column (a chemical reactor packed with reduced manganese) was used to obtain the Ar content. The columns and detectors were thermostatted at 70°C.

Since the ionization detectors are sensitive to carrier gas (neon) contamination, the whole GC system was pressurized during storage and flight. Eight samples were analysed from a 42 km altitude to the surface, with 18 chromatograms for the separation of sulfur compounds (first detector) and 27 for light gases (second detector). The GC of the Venera mission could not analyse for Ne, as this was used as the carrier gas. The Ar abundance (Table 3) was determined from its response as a negative peak. This

Table 3 Gas chromatography measurements of the lower atmospheric composition of Venus

	Mission				
	Pioneer-Venus			Venera 12	Vega
Altitude (km)	52	42	22	0–42	60–55
CO ₂ (% by volume)	95.4	95.9	96.4 ± 0.1		
N ₂ (% by volume)	4.60 ± 0.14	3.54 ± 0.04	3.41 ± 0.01	2.5 ± 0.5	
H ₂ O (% by volume)	<0.06	0.52 ± 0.07	0.135 ± 0.015	<0.01	
Ne (ppm by volume)	<8	11	4.3 ± 0.7		
O ₂ (ppm by volume)	44 ± 25	16 ± 7		<20	
Ar (ppm by volume)	60.5	63.8 ± 13.6	67.2 ± 2.3	40 ± 20	
CO (ppm by volume)	32	30 ± 18	19.9 ± 3.1	28 ± 14	
SO ₂ (ppm by volume)	<600	176	185 ± 43	130 ± 60	<100
H ₂ SO ₄ (mg m ⁻³) aerosol					~1

behaviour enabled estimation of the O₂ mixing ratio (<2.10–3.00% by volume) as the GC of Venera instrument did not directly measure O₂ concentration (O₂ coelutes with Ar). The values of Ar and O₂ mixing ratios lie in the same range of experimental error as the revised data of the Pioneer Venus GC.

Measuring atmospheric composition with different instruments is clearly advantageous, allowing cross-checks and preventing measurement errors. The quite good agreement of the data in Table 3 validates the results and gives a reasonable basis for models of Venusian atmospheric chemistry.

Vega GC Experiments

The two spacecraft of the Vega mission reached Venus in June 1985. The atmospheric probes (Vega 1 and 2) used a balloon to allow an hour's duration for the descent into the Venusian atmosphere. The SIGMA-3 GC on board each probe was designed by Mukhin and co-workers for the analysis of the gases and aerosols of the Venus cloud layer (60–55 km altitude). Three GC sub-units were arranged in parallel, each having a column connected to a different detector. Three different detectors were used: a helium ionization detector, a TCD and an electron-capture detector (ECD). The carrier gas was helium except for the sub-unit employing the ECD (carrier gas: ultrapure N₂). The separation of H₂S, COS and SO₂ in the presence of CO₂ and water vapour was performed at 70°C, with a column packed with a mixture of Porapak QS and Porapak N.

In the gas analysis mode, the sample was heated at 80°C and directly injected on to the column. At the sampling altitude (60–55 km) the experiment demonstrated the absence of H₂S, COS and SO₂ down to the detection limit of the GC instrument (10–100 ppm, depending on the substance). In the pyrolytic mode, the cell containing a carbonized fibre-glass filter was heated at 350°C. At this temperature H₂SO₄ is broken down into CO₂, H₂O and SO₂. The comparison of flight experiments with simulation data enabled estimation of the concentration of H₂SO₄ in the Venusian atmosphere to be about 1 mg m⁻³ for the 60–55 km altitude range.

Missions to Titan

Titan, a giant satellite of Saturn, has a dense atmosphere (Table 1). As with the Earth's atmosphere the main constituent is N₂. CH₄ is present at a low percentage. Traces of other organic compounds were revealed by Voyager's infrared spectrometer. The presence of these compounds was also predicted by Raulin and co-workers from the results of laboratory simulations. In addition, the atmosphere contains

aerosols and cloud droplets that obscure the surface of the satellite.

One of most important goals of the Cassini-Huygens mission to Titan is the *in situ* analysis of the composition of Titan's atmosphere. Successfully launched on October 1997, the NASA spacecraft (Cassini) carries a probe (Huygens) provided by the European Space Agency (ESA). After release from the orbiter in November 2004, the probe will slowly descend to Titan by deploying three parachutes. The six scientific experiments on the probe are designed to determine the physical and chemical properties of the atmosphere and the surface of Titan. Among these instruments are the GC-MS and the aerosol collector and pyrolyser (ACP).

Huygens GC-MS Experiments

The main objective of the GC-MS designed by Niemann and co-workers is to measure the chemical composition of the stratosphere and troposphere (from 170 km to the surface) during the 2.5 h descent. The GC-MS connected to the ACP will determine the nature and the abundance of the organic and inorganic compounds present in the atmosphere, both in the gaseous phase and in the aerosols themselves.

Three columns operating in parallel will be used to separate the expected species of Titan's atmosphere (Table 2). The identification and detection are achieved by connecting each column to an independent MS ion source. The MS (quadrupole, range 2–150 amu) will operate in two modes, either coupled to the GC or independently, by direct sample injection (Figure 1). For many substances (noble gases and many organics) mixing ratios as low as 0.1 ppb will be detected.

Capillary columns will be used for the first time for the *in situ* analysis of an extraterrestrial planetary atmosphere. Sternberg and co-workers selected the columns of the Cassini-Huygens mission for their compatibility with the severe constraints imposed by the experiment: fast analysis time, stability of the stationary phase (vacuum, cosmic rays, high energy electronic bombardment, inlet carrier gas pressure, 1.4–1.9 bar, outlet flow-rate of <1 mL min⁻¹, isothermal analysis in the range of 30–60°C. The first column, a carbon molecular sieve micro-packed column, will be used to separate light gases such as N₂ to CH₄. The second, a wall-coated open-tubular (WCOT) capillary column of glassy carbon will be used to separate low molecular mass hydrocarbons (C₁–C₃). The analysis of the saturated and unsaturated hydrocarbons (C₄–C₈) and the nitriles (up to C₄) will be achieved using a silicosteel WCOT capillary column having a slightly polar

stationary phase: cyanopropyl phenyl (CPP) dimethylpolysiloxane (DMPS) (Figure 2).

Aerosol Collector and Pyrolyser (ACP) Instrument

The ACP instrument was designed by Israel and co-workers to sample and collect the aerosols of Titan's atmosphere, and then to transfer the products from evaporation or pyrolysis to the Huygens GC-MS, for analysis. The aerosols are collected on a multilayered stainless filter by direct impaction for the first sampling (135–80 km). A pump is used at lower altitudes (80–32.5 km) and (22–17 km) to draw the atmosphere through the filters for the two other samplings. The filter is moved to an oven and heated at 250° or 600°C. Labelled nitrogen is used to transfer the gas and pyrolytic products to the GC-MS.

Each sample will be analysed using the direct MS mode. The GC-MS analysis will be performed once with the 600°C pyrolysis sequence. The tests for validating the ACP-GC-MS experiment were made by analysing the products synthesized by Raulin, Coll and co-workers when the photolytic and radiolytic processes expected in Titan's atmosphere were simulated (Figure 3).

Mission to Comets

It is generally believed that cometary nuclei, due to their formation in the outer solar system at very low temperatures, should retain the composition of the solar nebula and thus the average composition of the solar system. Considered as the most primitive bodies of the solar system, comets are believed to have seeded Earth with organic matter and water (Table 1) through numerous impacts on the surface of the primitive Earth. Therefore, cometary exploration is of primary importance for a better understanding of the solar system, as well as the origin of life on Earth. Following several cometary fly-by missions (e.g. Giotto, Vega) which provided the first images of a cometary nucleus and *in situ* measurements of the composition of gas and dust released from the surface, the ESA Rosetta mission will explore the nucleus of P/Wirtanen comet. The ESA Rosetta mission will be launched in 2003 and after two gravity-assisted fly-bys of Earth and Mars, it will reach the comet in 2011. The Rosetta mission will include a spacecraft and a landing probe for the *in situ* analysis of the cometary nucleus and its environment. The scientific

payload of the cometary lander includes two instruments for chemically analysing the surface.

The first experiment, named COSAC (cometary sampling and composition experiment), has been built by Rosenbauer and co-workers at the Max-Planck-Institut für Aeronomie (Lindau, Germany) and the second, Modulus (method of determining and

understanding light elements from unequivocal stable isotope compositions), has been built by Pillinger and co-workers at the Planetary Science Research Institute, Open University (Milton Keynes, UK). These two instruments will use state-of-the-art GC techniques, involving pyrolysis and MS.

Cometary Sampling and Composition (COSAC) Experiments

The COSAC experiments by Py-GC-MS are designed to analyse gases either sampled directly from the atmosphere around the nucleus, or provided by the heating of nucleus material collected by the lander's sampler which can drill to a depth of at least 20 cm.

The pyrolyser consists of micro-ovens, mounted on a carousel, which allow vaporization by stepwise heating of the cometary solid sample. The GC subsystem contains eight capillary columns divided into two packages of four sharing a common injector. Up to four columns, which can be selected individually, can be operated in parallel in the temperature range 0–200°C. GC detection is performed by miniature solid-state thermal conductivity detectors. COSAC can be used as a stand-alone instrument or can be coupled to the time-of-flight (TOF) MS. Five of the GC columns are WCOT and PLOT columns dedicated to general chemical composition analysis. In term of speed, efficiency, weight and carrier

Figure 3 GC-MS analysis of a gaseous sample obtained after irradiation (5 h spark discharge) of a gas mixture of N_2 (800 mbar) and CH_4 (13 mbar) at 100–150 K. Capillary column CP-Sil-5CB (25 m \times 0.15 mm). Carrier gas, He; temperature, 20°C, then programmed at low temperature (< 150°C). (Adapted from Coll P, Guillemin JC, Gazeau MC and Raulin F (1999) Report and implications of the first observation of C_4N_2 in laboratory simulations of Titan's atmosphere. *Planetary Space Science* 47: 1433–1440.)

gas flow-rate, these PLOT capillary columns will advantageously replace packed columns. The three other columns will be dedicated to the measure of chirality. Using chiral stationary phases they will be able to separate enantiomers, and thus determine the eventual presence of an enantiomeric excess.

Due to the large fraction (50%) of water vapour which is expected in the cometary sample, a single chemical water trap will be placed ahead of the columns. The mass of the COSAC experiment is constrained to 4.38 kg and the average power consumption during operation should not exceed 15 W.

The Modulus GC-MS Experiments

The Modulus experiments will determine the abundance and isotopic composition of major, minor and trace constituents of the cometary nucleus. It uses several analytical trains in parallel, each set composed of: chemical reactors to quantitatively chemically transform the cometary samples into very light volatile compounds, GC columns to purify and separate the resulting gases and detectors, including an ion trap MS, to quantitatively analyse these gases.

By converting the elements of interest into specific gases of low molecular weight such as O₂, CO₂, N₂ and CH₄, the Modulus experiment only requires a MS of low mass range with limited resolution. Thus, it uses an ion trap MS with a mass of 10–20 g (not including its power supply). The entire experiment could require less than 3 kg weight and 5 W of power. Two WCOT capillary columns, one of which has a ceramic coating stationary phase, will be used. Highly specific to volatiles (including permanent gases and water) this stationary phase is robust and withstands space constraints. It has to be noted that a variant of this experiment will equip the Orbiter craft to enable a comparative study between the chemical composition of the coma and the nucleus to be carried out.

Future Developments

Mars is the most interesting planet to study because it may once have had an atmosphere similar to that of the primitive Earth. In the next decade, an extensive space programme will be devoted to the exploration of the planet with the purpose of comparing its evolution with that of the Earth. The most consistent explanation for the Viking failure to detect organic molecules lies in photochemically produced oxidants (such as H₂O₂) which originated in the atmosphere and diffused into the soil, and are potential sources of degradation of organic compounds. Missions, such as the Mars Sample Return (to be launched in 2007) are now being planned with a landing probe

including an experiment for exobiological characterization of the Martian surface material. The objectives of these missions, in the frame of a large international programme involving NASA, ESA, CNES and other national space agencies, are to search for subsurface water as well as for traces of life (past and present), organic compounds and oxidants. Several instruments on board the lander, among them a Py-GC-MS, will perform an *in situ* analysis of the subsurface, at depths where the effects of ultraviolet radiation and oxidizing agents are negligible.

Space instrumentation, because of its many constraints, has brought about several technological developments in the field of chromatography and has opened the way for the chemical analysis of more complex compounds in extraterrestrial environments. But there is a need of new instrumentation for the analysis of non-volatile and/or thermally fragile organic compounds, such as amino acids, incompatible with pyrolysis techniques. The adaptation of high-performance liquid chromatography (HPLC) and supercritical fluid chromatography (SFC) to space conditions seems difficult. Chemical derivatization coupled to GC (CD-GC) might be the solution. The development of an automated chemical derivatization process is under investigation and could be used for the *in situ* analysis of the Martian soil in forthcoming missions to Mars.

Introduction

This review aims to summarize the application of gas chromatography (GC) to the analysis of steroids. The review concentrates mainly on hyphenated GC–mass spectrometry technology as the use of GC linked to detectors other than mass spectrometry (MS) is now decreasing. A survey of literature using MEDLINE indicated that in the period 1990 to date, more than 90% of around 400 references used GC–MS, as might be expected as the mass spectrometer is now the most effective detector for GC and simple, cheap and sensitive bench-top GC–MS systems are now widely available. Use of MS can often compensate for poor GC resolution or peak shape, but use of GC–MS still requires that attention is paid to optimization of both GC and MS behaviour, if maximum sensitivity is required. The MS, of course, has the added advantage that it can provide structural data and can be used to confirm that a GC peak is indeed a steroid. By com-

paring the mass spectrum obtained with those in a library can often identify the steroid. Retention time data, on their own, are not a satisfactory criterion for identification but can be considerable value when combined with MS data.

Steroids range from the C_{18} oestrogens to C_{27} sterols such as cholecalciferol (vitamin D) and include androgens, progestagens, corticosteroids and bile acids as well as a large number of synthetic steroids, some of which may be used therapeutically. The formulae of some of these steroid types are illustrated in Figure 1 in III/STEROIDS/Liquid Chromatography and Thin-Layer (Planar) Chromatography. Alternatively readers can consult the *Dictionary of Steroids*, which lists some 10 000 steroids together with their formulae, trivial and systematic names and other useful information.

Derivatization

Most steroids have melting points in excess of 150°C (estradiol-17 β , the female sex hormone, for example, has a melting point of 176°C). It is therefore often necessary to derivatize steroids of interest in order to optimize their GC performance. Derivatization improves volatility, a necessary characteristic as the analyte in GC must be in the vapour phase. High injection (around 350–400°C) and column temperatures (up to 350°C) may also be necessary to achieve

separation, especially of higher molecular weight steroids and their derivatives. The raised temperature necessary to achieve satisfactory separation, also brings with it the problem of analyte decomposition, although decomposition should not be taken to mean destruction. It is, for example, possible to separate oestrogens and androgens and some progestagens without derivatization, but 17-hydroxylated C_{21} steroids (such as cortisol) undergo thermal side-chain cleavage and cholecalciferol (vitamin D_3) and its metabolites all undergo B-ring closures, giving rise to two isomers, even when derivatized. Such characteristic reactions may often have useful diagnostic features. It is also possible to enhance particular thermal reactions such as dehydration by the use of catalysts in order to obtain quantitative conversion in the injection port to dehydration products, which may have improved MS characteristics. 25-Hydroxyvitamin D_3 can be analysed in this way using aluminium powder in the injection port and the dehydration product has intense high mass ions which improve sensitivity of MS detection and of course time-consuming derivatization is avoided. Figure 1 illustrates this particular example.

Derivatization also improves GC peak shape as the presence of hydroxyls increases adsorption during chromatography and at very low concentrations this adsorption may give rise to a nonlinear response. In addition, if GC-MS is to be used, the appropriate choice of derivative may also have a profound influence on sensitivity and/or specificity of detection. An example of this is given in Figure 2, where the mass spectrum of the 3,17 β -di(trimethylsilyl) ether of 19-nor-androsterone is compared with the spectrum from the 17 β -trimethylsilyl (TMS) ether. In this example (this is the urinary metabolite which is measured in order to confirm abuse of the anabolic steroid nandrolone), it can be seen that the intensity of the two high mass ions in the di-TMS ether (which is a 3-enol ether) are considerably greater than those for the mono-TMS ether, allowing greater sensitivity and specificity of measurement. Table 1 lists some of the common methods of derivatization, which protect against adsorption and decomposition and at the same time improve MS characteristics. Negative-ion chemical ionization (CI) techniques, which use soft ionization and yield predominately the molecular or pseudo-molecular ion, can provide very sensitive assay methods but require the presence of electron-capturing moieties. Most steroids do not possess these and derivatization is often used in this context to provide steroid derivatives containing the necessary chlorine, iodine or bromine atoms (e.g. perfluoroacyl or chloro- or iodomethyldimethylsilyl ether derivatives). For the higher energy electron im-

Figure 1 On-column quantitative dehydration of underivatized 25-hydroxyvitamin D_3 using aluminium powder in the injection liner. (Upper panel) EI(+) mass spectrum of the dehydration product(s) – there are at least two dehydration products, which do not separate, but only one is illustrated. Note the greatly increased intensity of the molecular ion – m/z 364. (Lower panel) Single ion monitoring of m/z 364, indicates only a single peak. (From G Jones *et al.* In: *Modern Chromatographic Analysis of Vitamins* (eds A DeLeenheer, WE Lambert and HJ Nellis), 2nd edn. New York: Marcel Dekker, 1992, with permission of authors and publisher.)

pact ionization (EI), halogenated derivatives are not necessary and hydroxyl groups are usually derivatized as TMS ethers and oxo groups as O-methyloximes (or enolized to give enol-TMS ethers). Mixed derivatives are also used (e.g. O-methyloxime-TMS derivatives) and in this example the oxime is formed first and protects the oxo group against subsequent enolization by the silylating reagent.

17-Hydroxylated C_{21} steroids are thermostable when derivatized as 17-TMS-ethers-20-oximes and can thus be analysed without degradation. Steroid carboxylic acids (e.g. bile acids) will not run in GC systems except as aliphatic esters (usually this means formation of methyl esters as otherwise molecular weight and thus retention time increases). Other esters have, however, been used for GC of faecal extracts to separate the bile acids from the neutral sterols, which are insufficiently resolved as methyl-TMS ethers. Use of *n*-butyl-TMS ethers increases the

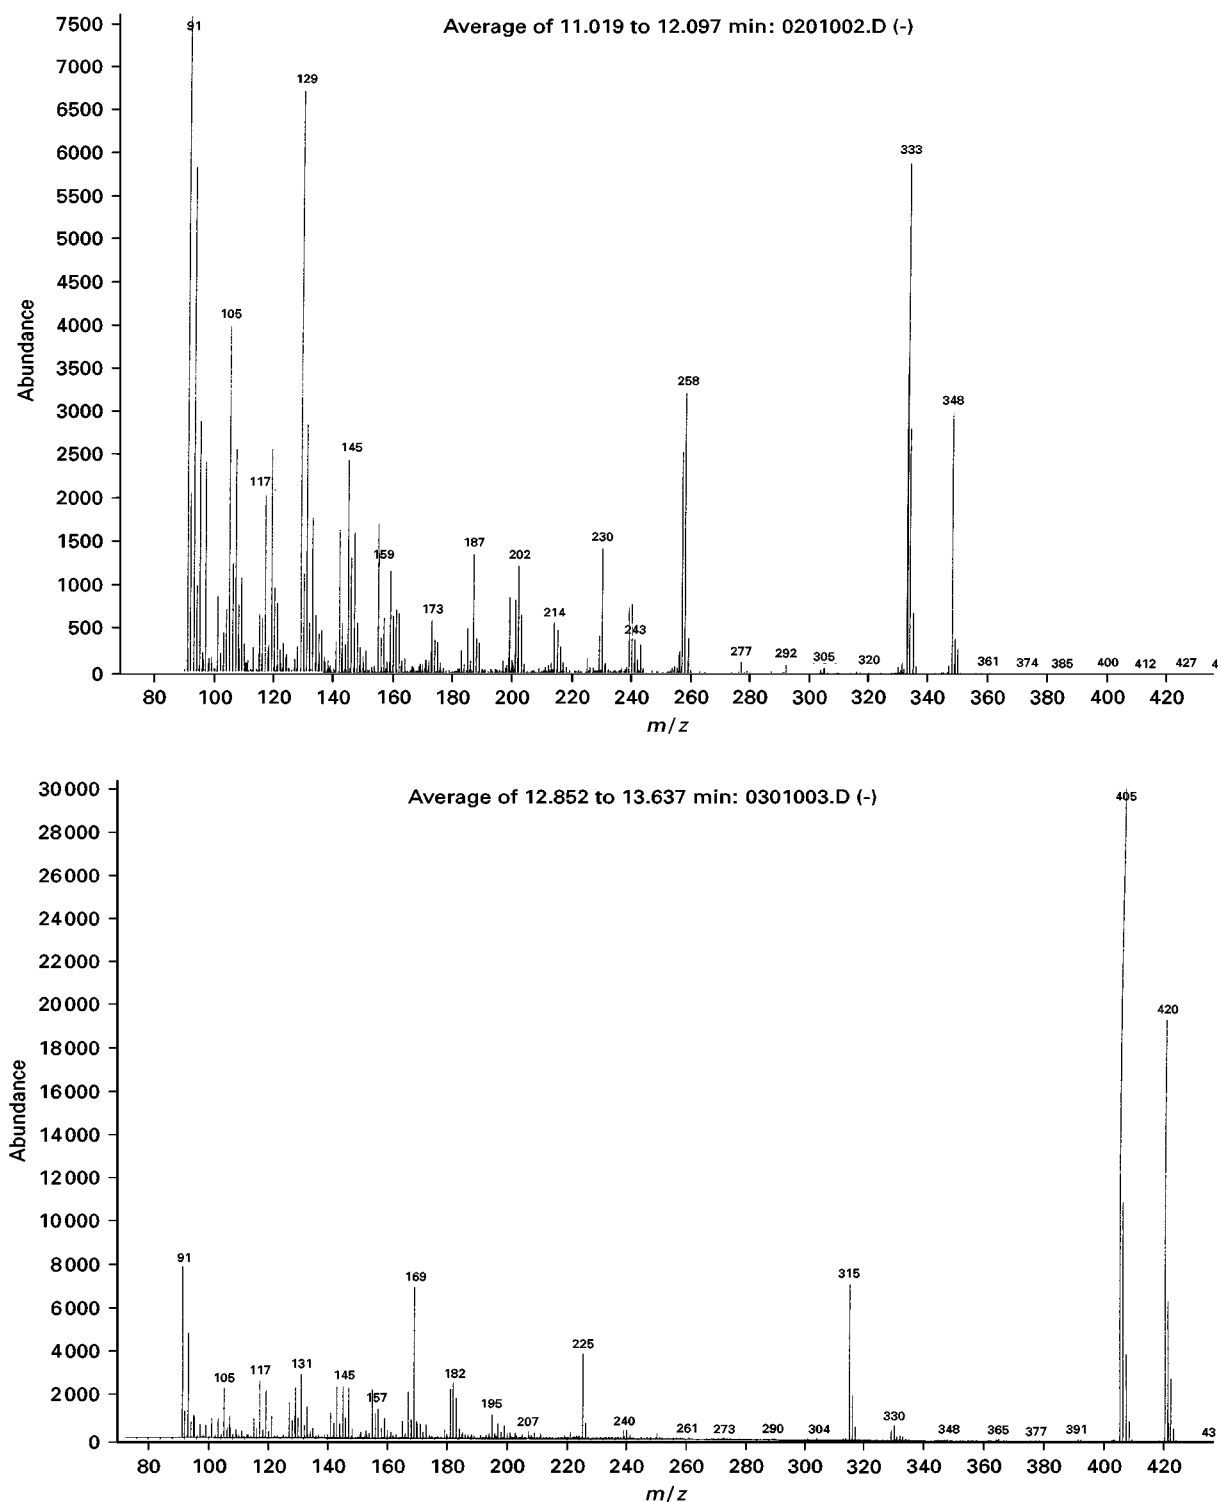

Figure 2 Enhanced sensitivity of detection of the anabolic steroid, nandrolone, by formation of different derivatives. (Top) EI(+) mass spectrum of the 17 β -trimethylsilyl ether and (bottom) EI(+) mass spectrum of the 3-enol, 17 β -di(trimethylsilyl) ether. It can easily be seen that the two ions at m/z 405 and m/z 420 of the di-TMSI carry more of the total ion current than the corresponding ions (m/z 333 and m/z 348) of the mono-TMS. These mass spectra were produced using equal amounts of nandrolone and the ion at m/z 91 offers a useful index for comparison. (With permission of Mrs J Nolan.)

retention time of the bile acids sufficiently to separate them from the sterol-TMS ethers. This is illustrated in Figure 3. Other derivatives have also been used which

are selective for particular parts of the steroid structure, such as formation of cyclic boronates across vicinal hydroxyls. Such derivatives being selective

Table 1 Some derivatization procedures used for the GC and GC-MS analysis of steroids. This list is not comprehensive but includes the majority of the most popular derivatives

<i>Steroid group</i>	<i>Derivative</i>	<i>Formula*</i>

are diagnostic of structure and may also have the advantage of improving sensitivity and specificity of measurement.

Column Performance

For good GC performance, the intention is to obtain symmetrical peaks with retention times as short as necessary to achieve the desired separation. In the past considerable attention was paid to the development of different stationary phases in order to optimize resolution but the advent of capillary column and their linkage to MS systems has reduced the need for new stationary phases. Although capillary columns with a variety of bonded stationary phases are available, most GC-MS systems for steroids use non-selective (nonpolar) methylsilicone phases (e.g. HP1 columns from Hewlett-Packard), although more polar phases may be necessary for particular separations (i.e. C_{20} steroid carboxylic acids). Columns are usually around 15–30-m long (i.d. 0.2–0.4 mm with film thickness from around 0.1 μm upwards) and carrier gas flow rates are 1–2 mL min^{-1} , allowing direct insertion of the column exit into the ion source of the mass spectrometer. There are numerous means of sample injection but we have found the easiest to be direct on-column splitless injection using a syringe. For optimum chromatographic performance, we have found that the injection temperature is best kept at 400°C and that the choice of solvent can also have influence. This high temperature causes considerable

problems in that most injection port septa are not suitable and breakdown products cause interference. This has been overcome by use of a septumless injection system (JADE injector) in which the syringe needle injects onto the column through two stainless-steel ball-bearings, which form the back-pressure seal. Other injection procedures have found favour in the steroids field, all of which strive to inject as much of the extract as possible. These systems include a dropping glass needle in which the sample is loaded into small glass capillaries which can be automatically loaded sequentially into the heated zone of the injector. Cold trapping splitless injection has also proved useful in that it allows for the on-column injection of relatively large volumes of solvent into silanized glass liners. Injection systems which load the whole of the extract onto the top of the column necessarily shorten column life and for quantitative work, column deterioration must be monitored to achieve consistent and high sensitivity. When deterioration is detected, the column can be regenerated by removal of the top 10 cm or so but this may lead to alteration in retention characteristics of steroid derivatives.

Prior to GC analysis, steroids must be extracted and purified, the degree of purification depending upon the specificity of the detector system employed. Specific GC-MS systems require less pre-purification but the possible contamination of the MS ion source must always be considered. Extended column life and increased periods between ion source cleaning are

Figure 3 GC chromatogram of sterols and bile acids present in stool from a healthy control. 10 mg of freeze-dried stool containing 20 μ g nor-cholic acid was subjected to derivatization. After dissolving in 200 μ L hexane, 1 μ L was injected into the GC column. Chromatographic and derivatization details can be found by consulting the original paper. Peak identification: 1, nor-cholic acid; 2, lithocholic acid; 3, iso-deoxycholic acid; 4, deoxycholic acid; 5, chenodeoxycholic acid; 6, cholic acid; 9, 3-oxo,12 α -hydroxy-5 β -cholanoic acid; 10, 12-oxo-lithocholic acid; a, coprostanol; b, cholesterol; c, 24-methyl-coprostanol; d, campesterol; e, 24-ethylcoprostanol; f, stigmasterol; g, sitosterol; h, sitostanol. (From AK Batta *et al* (1999) *Journal of Lipid Research* 40: 1148–1154, with permission of authors and FASEB.)

obtained if attention is paid to pre-column purification. Silylating reagents should also be removed prior to injection by use of small Lipidex 5000 columns, unless they are sufficiently volatile not to cause a problem. Trimethylsilylimidazole, a valuable reagent for the formation of TMS ethers on sterically hindered hydroxyls (e.g. at positions C11 β , C17 α , C25), must be removed before GC–MS, whereas N-methyl-N-trimethylsilyltrifluoroacetamide (MSTFA) can be injected directly. Steroid glucuronides and sulfates must be hydrolysed prior to GC as they do not run in GC systems unless special derivatization methods are adopted. While we have found trimethylsilyl ethers to be stable, others have not. It is advisable therefore to store and inject steroid TMS ethers in MSTFA.

Mass Spectrometry and Other Detectors

The GC of steroids can be carried out with a variety of detectors, flame ionization (FID) being the most

widely used today. Electron-capture detectors (ECD) which were commonly used in the past to improve sensitivity of detection, have now largely been replaced with negative ion chemical ionization (CI) mass spectrometry. Selective detection of steroid oximes can be accomplished using nitrogen-phosphorus detectors. Today, however, the mass spectrometer in various forms offers the most versatile detection system for GC, providing improved selectivity and sensitivity in comparison to other detectors. Because of the successful development of immunoassays for most of the clinically important steroids, GC has not in recent times found much application for individual steroid analysis, although occasional publications can still be found. However, the advent of capillary columns with immense resolving power suggested the possibility of utilizing GC as a means of examining in a quick and simple way, the complex patterns of steroids in human urine and how they change in disease states. In the late 1970s Shackleton, utilizing the pioneering work of Gardiner and Horning of ten years before, introduced the concept of urinary steroid profiling. Urinary steroid extracts (with or without β -glucuronidase hydrolysis) were derivatized to form steroid O-methyloxime-TMS ether derivatives and analysed using capillary open-tubular columns monitoring the analytes by flame ionization detection. Use of two internal standards allowed the quantification of 23 different steroids in children with various steroid abnormalities. These robust techniques are still in use today and provide valuable information to assist clinical diagnosis and monitoring of treatment and modern data handling technology has greatly eased the task of interpreting these complex profiles. The urinary profiling technique also allows identification of unknown peaks in the extract, when the original flame ionization detector is replaced with a mass spectrometer. An example of this methodology is illustrated in **Figure 4**. Further information about this valuable approach to urinary steroid analysis by GC–MS and its application in the diagnosis of steroid related disorders can be found in Shackleton's article in the Further Reading section.

The necessary process of purification and derivatization means that for quantitative work, suitable internal standards must be used. For GC–MS the best internal standards are of course stable isotope (deuterium or carbon-13) labelled analogues of the analyte. In these situation at least three isotopic atoms must be incorporated and the percentage of the triply labelled standard (i.e. in the case of deuterium labelled, d_3) should be greater than 99%. Deuterium labels are usually introduced by acid-catalysed deuterium exchange and thus the label may not be

Figure 4 Steroid profiles by gas-liquid chromatography obtained from urine samples from (upper trace) a normal adult and (lower trace) a 16-year-old male with congenital adrenal hyperplasia (21-hydroxylase deficiency). Steroids were extracted with Sep-Pak C18 cartridges and after hydrolysis of glucuronide and sulfate conjugates, re-extracted and O-methyloxime-trimethylsilyl ether derivatives were formed. These were analysed by GLC using an OV1 capillary column. The major metabolites of 17-hydroxyprogesterone (the substrate of the 21-hydroxylase enzyme) are named in the lower trace. Other peaks are as follows: A, B and C: internal standards, androstanediol, stigmasterol and cholesteryl butyrate; 1: androsterone; 2: aetiocholanolone; 3: dehydroepiandrosterone (DHEA); 4: 11-oxo-androsterone; 5: 11 β -hydroxy-androsterone; 6: 11 β -hydroxy-aetiocholanolone; 7: 16 α -hydroxy-DHEA; 8: pregnanediol; 9: pregnanetriol; 10: androstenetriol; 11: tetrahydrocortisone; 12: tetrahydro-11-dehydrocorticosterone; 13: tetrahydrocorticosterone; 14: *allo*-tetrahydrocorticosterone; 15: *allo*-tetrahydrocortisol; 16: α -cortolone; 17: β -cortolone + β -cortol; 18: α -cortol. (Kindly provided by Dr Norman Taylor, King's College School of Medicine and Dentistry.)

stable in acid conditions. Ideally ^{13}C -labelled standards are to be preferred but this requires incorporation into the nucleus of the steroid which can only be achieved by extensive synthetic chemistry. All ster-

oids are analysed by GC-MS in the same way and the criteria used to ensure specificity/accuracy are those adopted by the Substance Abuse and Mental Health Services Administration (SAMHSA) for drug confirmation in employee drug-screening programmes – two, but preferably three, specific ions (with as high a mass : charge ratio as possible) must be monitored and the results derived from each ion must not deviate by more than 10% from the mean. **Figure 5** illustrates the chromatograms obtained by multiple ion detection, monitoring two of the relevant ions of the analyte (25-hydroxyvitamin D_3) and the equivalent two ions from the hexadeuterated internal standard present in a plasma sample extract. In this example the standard curve relating peak height ratio (analyte : internal standard against mass of standard analyte) was linear and the intercept was not significantly different from zero.

Isotope dilution GC-MS is widely acknowledged as the gold standard of steroid analysis and is used as a means of providing target values for external quality-assurance schemes and for the confirmation of immunoassay screening procedures for drugs of abuse. **Table 2** gives brief details of the application of this methodology to the analysis of steroids in body fluids, which are taken from papers in the literature published between 1998–1999 and use both stable isotope-labelled and unlabelled internal standards. The availability of accurate and precise methods of steroid analysis by GC-MS is becoming of increasing public interest as the number of sportsmen and women in whose urine metabolites of anabolic steroids are found, continues to increase. It is clear that it is important for steroid (and other) drug testing that proper methodology for both qualitative detection and quantitation is available and this methodology can withstand public scrutiny. GC-MS provides precisely this. Excellent and up to date reviews of the application of GC and GC-MS to the analysis of steroids can be found in the Further Reading.

Mass Spectrometry for Structural Analysis

The other important aspect of GC-MS, apart from providing a high specificity method of steroid assay, is the role of MS as a means of identifying both known and unknown steroids. The use of the GC in this context is simply a means of delivering a relatively purified steroid derivative to the MS. The present author and his colleagues have successfully used GC-MS as a means of studying the metabolism of calcitriol analogues in target tissues and while the illustrations given are derived from these studies, they have wider application and the methodology used can

Figure 5 Isotope dilution mass fragmentography of 25-hydroxyvitamin D₃. GC was carried out after formation of per-trimethylsilyl ether derivatives using a non-selective OV1 column. An internal standard, [25,26-²H₆]25-hydroxyvitamin D₃, was added to the plasma sample prior to extraction and purification. The GC column was inserted into the ion source of the mass spectrometer and four ions were monitored (m/z 413 and 439 from the analyte and the corresponding ions, m/z 419 and m/z 445, from the internal standard). It will be noted that the hexadeuterated internal standard runs slightly earlier than the non-deuterated analyte. In this case the ratio of peak areas of analyte to internal standard gave a straight-line response which went through zero. Only two ions were monitored in this example whereas increased specificity can be obtained if three are monitored. The major peaks, the pyro-isomer and the isopyro-isomer, can be seen at approximately 11.20 min. Both peaks have a cyclized B-ring.

Table 2 Some examples of methods for the measurement of steroids by gas-liquid chromatography, published in 1998–1999

<i>Subject</i>	<i>Column details</i>	<i>Derivatives used</i>	<i>Internal standard</i>	<i>Detection</i>
Urinary steroid metabolite analysis	Non-selective methylsiloxane and 5% phenylmethylsiloxane 17 and 25 m × 0.2 mm	O-methyloxime-trimethylsilyl ethers	Androstanediol, stigmasterol and cholesteryl butyrate	Flame ionization detection* or mass spectrometry (EI+)
Ovarian steroids in the catfish	15 m DB1 column	O-methyloxime-trimethylsilyl ethers	None given	Mass spectrometry (EI+)
3 α -Reduced neuroactive steroids in human plasma	30 m × 0.25 mm with 0.2 μ m film thickness – HP5	O-methyloxime-heptafluorobutyrate esters	None given	Mass spectrometry (EI+)
Anabolic steroid metabolites in urine	30 m × 0.2 mm with 0.33 μ m film thickness. 5% phenylmethylsiloxane (ultra-2)	Pentafluoropropionates	[1,2- ² H ₂]-Testosterone	Mass spectrometry (CI–) using methane as reagent gas)
Detection of exogenous testosterone administration	DB7 (50% phenylmethylsiloxane). 30 m × 0.25 mm with 0.15 μ m film thickness	Acetates	Not relevant as only ¹³ C/ ¹² C ratios being measured	Mass spectrometry – combustion isotope ratio
Endogenous 19-nor-androsterone and aeticholanolone in human urine	HP1 30 m × 0.25 mm with 0.25 μ m and HP5 (5% phenylmethylsiloxane) 25 m × 0.2 mm with 0.33 μ m	Trimethylsilyl ethers (enols) and t-butyl-dimethylsilyl ethers	Trideuterated 19-nor-aeticholanolone	Mass spectrometry (EI+)
Serum DHA and DHA sulfate	DB5 30 m × 0.25 mm with 0.25 μ m film thickness	No derivatization	Androst-5-en-3 β -ol-16-one methyl ester	Ion trap mass spectrometry (EI+)
Testosterone: epitestosterone in equine urine	17 m × 0.2 mm with 0.11 μ m film thickness (5% phenyl-methylsiloxane)	3-Trimethylsilyl ether-17-pentafluorophenyldimethylsilyl ether	Not applicable as ratio being measured	Mass spectrometry (EI+)
Testosterone in hair	Optima 1 25 m × 0.2 mm with 0.1 μ m film thickness	Heptafluorobutyrate	Trideuterated testosterone	Mass spectrometry (EI+)
Urinary 3-oxo- Δ^4 -bile acids	30 m × 0.2 mm methylsiloxane	Carboxylic acid methyl ester-dimethylethylsilyl ether and O-methyloximes	3 α ,7 α -Dihydroxy-24-nor-5 β -cholanolic acid	Mass spectrometry (EI+)
Biliary elimination of endogenous 19-nortestosterone	None given	Heptafluorobutyrate	Trideuterated 19-nortestosterone	High-resolution mass spectrometry (EI+)

*See Figure 4 which illustrates the application of GC–FID for urinary steroid analyses.

DHA, dehydroepiandrosterone.

be applied to all steroids and their metabolites. Figure 6 shows the GC trace of calcitriol (1,25-dihydroxyvitamin D₃) as the per-trimethylsilyl derivative. Two peaks are always seen, as B-ring cyclization which occurs at the high temperature of the injection port quantitatively produces pyro- and isopyro-isomers which are always formed in the same ratio. Thus for every vitamin D-like compound, two GC peaks are observed. It is the pyro-peak which predominates and Figure 6 also shows the EI(+) mass spectrum derived at the apex of the pyro-peak after background subtraction. For the purpose of structural analysis, EI(+) spectra are preferable to CI spectra as CI is a much softer technique giving less

useful fragmentation – a similar objection applies to LC–MS, which also uses soft ionization. It is of course also possible to obtain a spectrum of the un-derivatized, albeit cyclized, calcitriol by ignoring the GC and inserting the calcitriol into the ion source of the MS by direct probe. This gives a molecular ion (M⁺) of 416. Examination of the mass spectrum of the per-TMS derivative shown in Figure 6 indicates a molecular ion of 732. Knowing that each TMS formed increases the molecular weight by 72 amu, it is possible to calculate the number of hydroxyl groups in an unknown compound (632 – 416 = 216 and 216/72 = 3). Metabolism of calcitriol and its analogues usually involves cytochrome P450-catalysed

Figure 6 EI(+) mass spectrum of 1,25-dihydroxyvitamin D₃. The total ion current is shown in the upper panel indicating the two cyclized isomers (pyro- at 10.90 min and isopyro- at 11.64 min) which are formed. In the lower panel is the mass spectrum of the per-trimethylsilyl ether of the pyro-isomer.

hydroxylation(s). The number of hydroxylations can be determined by the same procedure described above and if the MS of the per-TMS of the substrate is known, direct probe MS is not necessary. However further interpretation of the MS becomes necessary in order to decide where on the steroid molecule the hydroxylation has occurred. It is clearly also possible to deduce the presence of an oxo group as this increases the molecular ion of the substrate by 14 amu but again knowledge of the presence of this group does not determine its position. To carry out these calculations, it is necessary to be able to determine the molecular ion value. It is not always possible to do this directly as the mass spectra of the steroids usually have very low intensity molecular ions. However, as can be seen in Figure 6, all these cyclized steroid-TMS ethers have a prominent (M-131)⁺ ion, which is usually derived from A-ring cleavage, as well as (M-90)⁺ ions, derived by successive loss of silanols. It is therefore possible even in the absence of discernible M⁺ ions in the spectrum, to determine the *m/z* value of the molecular ion.

For the identification of the position of extra hydroxyls and oxo groups or even truncation, where cytochrome P450 lyases have cleaved the side chain, GC retention time data can prove extremely useful. Hydroxylation increases retention time but the fur-

ther out along the side chain (distal) the hydroxylation is, the longer the retention time. Truncation, by reducing molecular weight, clearly decreases retention time. Retention time, although useful is not sufficient on its own and further study of the fragmentation data has to be made. Further examples can be obtained by consultation of the texts listed in the Further Reading section. Consideration should also be given to the use of chemical reactions which modify the molecule under investigation. Reduction of oxo groups with sodium borohydride and subsequent derivatization as TMS ethers and GC-MS provides further evidence of structure. Cleavage of carbon-carbon bonds between vicinal hydroxyl groups with periodate can also provide valuable information about the site of hydroxylation if the reaction product is subsequently derivatized and subjected to GC-MS.

A very good example of the interpretation of mass spectra obtained from GC-MS of per-TMS derivatives is given in Figure 7. The metabolites illustrated here are all mono-hydroxylated metabolites of 1 α -hydroxyvitamin D₃ and thus give the same value of 632 amu for their molecular ion. All four metabolites show the characteristic (M-131)⁺ ion at *m/z* 501 as well as (M-90)⁺, 542 and (M-90-90)⁺, 452. The abundance of the M⁺ ion is, as usual, very low but it can easily be confirmed as being the ion at *m/z* 632 by

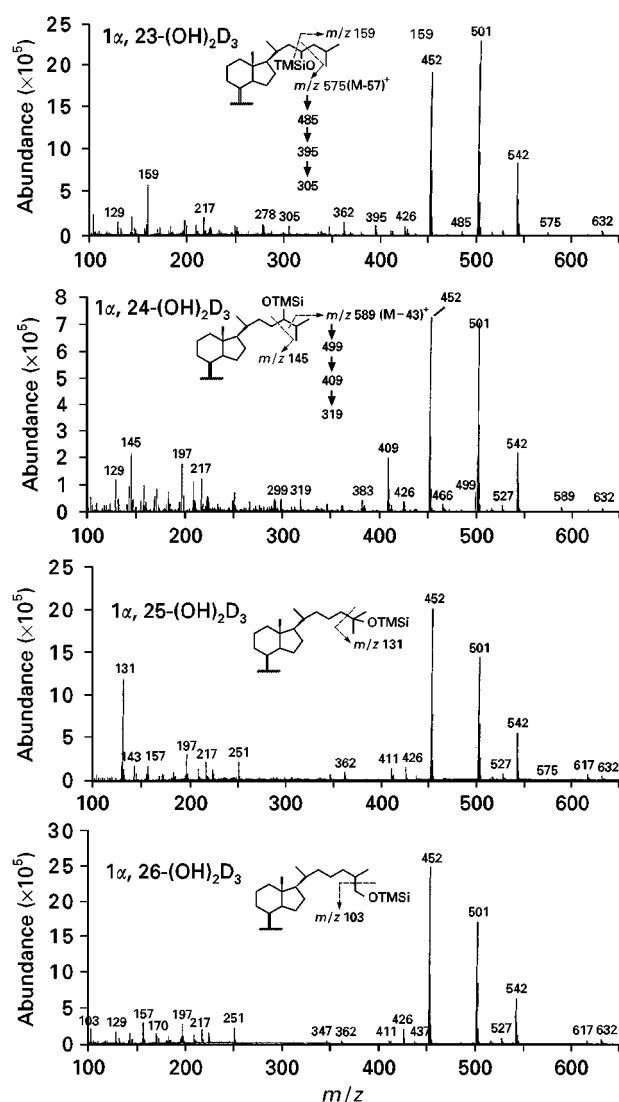

Figure 7 The EI(+) mass spectra of metabolites of 1 α -hydroxyvitamin D₃ (1 α -OHD₃). GC-MS was carried out after derivatization to form the per-trimethylsilyl ethers. Both pyro- and isopyro-isomers of each metabolite were observed but the mass spectrum of the pyro-isomer (the major peak) is shown in each case. The major ions (m/z 632 (M^+), m/z 542, 432 and 362 (not highlighted) (M^+ losing successive silanols) and m/z 501 (M^+ losing 131 by A-ring cleavage) are the same in all the spectra. m/z 217 is the characteristic ion always seen in these 1,25-dihydroxylated steroids and m/z 251 (not highlighted) arises by side-chain cleavage and subsequent loss of three silanols. It is however possible to distinguish each isomer from the characteristic fragmentation patterns illustrated for each above the appropriate spectrum. (From G Jones and HLJ Makin (2000) In: *Modern Chromatographic Analysis of Vitamins* (eds A DeLeenheer, WE Lambert and HJ Nellis), 3rd edn. New York, Marcel Dekker, to be published, with permission of authors and publisher.)

consideration of the origin of the more abundant ions. Although not shown here, the retention times increase as the hydroxylation position moves distally along the side chain. It is the presence of other less abundant ions of lower m/z value, which are diagnos-

tic for the position of the hydroxyl on the side chain and the derivation of these ions is shown in the fragmentation patterns illustrated in Figure 7. Many other examples of this sort of elucidation of seco-steroid structure can be given, all of which rely on the same sort of approach.

Routine steroid analysis at ng mL⁻¹ concentrations by GC-MS utilizes low-resolution mass spectrometry but there are occasions when increased sensitivity is required for the detection/measurement of steroids at concentrations in the pg mL⁻¹ range. This can be achieved by using high-resolution (double-focusing)

Figure 8 High-resolution mass fragmentography of an extract of serum from a patient taking vitamin D₂, showing ion chromatograms of per-trimethylsilylated (TMS) ether of putative 1 α ,24-(OH)₂D₂, monitoring three separate ions, m/z 513.3584 (A), m/z 554.3975 (B), and m/z 601.3929 (C), showing the trace between 9 and 14 min. The peaks from the pyro-isomer of 1 α ,24-(OH)₂D₂-TMS are shaded. The ion ratios in this extract are the same as those in the mass spectrum of the authentic compound. (From EB Mawer *et al.* (1998) *Journal of Clinical Endocrinology and Metabolism* 83: 2156-2166, with permission of authors and publisher.)

instruments which, although they increase specificity, reduce overall sensitivity but paradoxically allow increased sensitivity of measurement by increasing the signal : noise ratio. GC-HRMS has successfully been used for the measurement of a calcitriol analogue, hexafluorocalcitril, with a minimum detectable limit of 2 pg mL^{-1} , which gives this assay the sensitivity to measure plasma calcitriol itself, which circulates at concentrations around 30 pg mL^{-1} . This principle is, of course, generally applicable and most steroids can be detected at lower concentrations by the use of GC-HRMS. This technique has been used mainly by laboratories interested in the detection of anabolic steroids in athletes' urine (e.g. metandienone, stanozolol and clostebol) as a means of detection of drug abuse in sport but also as a means of detecting illicit steroid administration to cattle (4-chlorotestosterone). It has occasionally been suggested, as in the case of nandrolone, that metabolites observed have arisen *de novo* by *in vivo* metabolism from other steroids rather than from exogenous sources. Use of GC-combustion-MS (isotope ratio mass spectrometry) has been shown, by measuring the $^{12}\text{C} : ^{13}\text{C}$ ratios, to have considerable potential as a means of distinguishing between exogenous and endogenous sources. Figure 8 gives a further example of the sensitivity of GC-HRMS which was used to demonstrate the presence of $1\alpha,24$ -dihydroxyvitamin D_2 in human plasma by focusing on three specific ions and demonstrating that they had a retention time the same as the standard and were present in the same ratio and as they were in the MS of the pure standard. Similar studies with low-resolution MS detection were unable to demonstrate the presence of this steroid.

Conclusion

GC-FID of steroids is today primarily confined to the analysis of urinary steroid profiles, a technique introduced in the 1980s but, as a brief examination of the recent literature will show, still produces valuable

clinical information today. Much improved data are obtained when the GC is interfaced with the a mass spectrometer, allowing greater sensitivity and specificity of detection with the added benefit of structural information about unknown steroids. It is interesting to note that C_{21} steroids are usually analysed by immunoassay or LC-MS whereas GC-MS is still widely used for the specific analysis of oestrogens and androgens, particularly in the sports area where the definitive detection of anabolic steroids is required. GC-MS, particularly when high-resolution MS is used, is still more sensitive than LC-MS for steroid assay and EI(+) ionization methodology provides more useful structural information than can be achieved with LC-MS or even LC-MS-MS. It will be interesting to see whether GC-MS will hold its own against LC-MS over the next ten years.

Introduction

This review aims to summarize the application of liquid chromatography (LC) in all its forms, including thin-layer chromatography (TLC), for the analysis of

steroids. As LC relies on either adsorption or partition, extraction of the analyte from the matrix, a similar process, has been considered, as has the necessary final step of LC-quantitation. Readers who seek further information are encouraged to use the texts given in the Further Reading section, which are valuable sources of information from which original research references can be obtained as well as information about alternative means of steroid analysis.

Steroids comprise a large group of compounds which occur naturally in both plants and animals. Their structures are all based upon the cyclopentanoperhydrophenanthrene nucleus and all the naturally occurring steroid hormones are synthesized in humans *in vivo* from cholesterol. Some steroid hormones – those derived from vitamin D₃ which are derived from cholesterol precursors – have a broken B-ring and are described as secosteroids. Various

chemical modifications of the nucleus can be made by increasing the size of the rings or modifying them in some way to produce large numbers of synthetic steroids. As an illustration of the wide variety of steroids which are available today, the *Dictionary of Steroids* lists around 10 000 compounds. Steroids have a wide spectrum of therapeutic uses and this has encouraged the synthesis of large numbers of synthetic steroids in an attempt to enhance or depress

Figure 1 Formulae of some naturally occurring steroids. The numbering system used to identify the individual carbon atoms in the steroid skeleton is also illustrated.

particular physiological responses. From the point of view of a person working in a biomedical environment, the naturally occurring steroids are of particular interest and these include the gluco- and mineralo-corticoids secreted by the adrenal cortex, the sex hormones produced in the gonads, progesterone synthesized in the placenta and the bile acids which aid the digestion of fats. The parent compound of all these naturally occurring human steroids, cholesterol, is an integral part of the structure of cell membranes. The nomenclature of steroids is complicated by the fact that trivial names of many important steroids (see, for example, cortisol and testosterone in Figure 1) are still widely used. There are agreed IUPAC rules for the nomenclature of steroids but application of these rules gives rise to long and cumbersome names. Readers who are unfamiliar with steroid nomenclature are referred to the *Dictionary of Steroids* which contains a very useful summary. Figure 1 also illustrates the numbering of some of the important carbons in the steroid nucleus.

It has been estimated that, of the armoury of therapeutic drugs available for prescription in the UK, around 25% either are or contain steroids in their formulation. Because of the physiological and therapeutic importance of steroids and the huge number of different steroids which one may encounter, they represent a considerable analytical challenge. In this short summary of the liquid chromatographic methods for the separation of steroids, attention will be devoted in the main to the separation and quantitation of the naturally occurring steroid hormones and bile acids. Figure 1 gives the structures of some of the important steroids which are found in human serum and examples of their conjugates. Readers who wish to learn more about the infinite variety of steroids are referred to the classic organic chemistry text by Fieser and Fieser and the *Dictionary of Steroids*. A text on the Biochemistry of Steroid Hormones is given in the section on Further Reading.

Steroids are in the main hydrophobic, a property conferred by the nucleus, and this hydrophobicity is modified by hydroxyls and oxo groups on the periphery of the nucleus. Steroids are often conjugated with glucuronic and sulfuric acids, particularly through the hydroxyl at carbon 3. These conjugates are of course more water-soluble than the unconjugated steroid. The side chain attached to carbon 17 of the nucleus in cholesterol contains a further 10 carbons and this side chain is *in vivo* enzymatically cleaved between C₂₄ and C₂₅ to produce the C₂₄ bile acids and between C₂₀ and C₂₂ to produce steroid hormones. The C₂₄ carboxyl can also be conjugated with glycine and taurine which again increase the water-solubility of these molecules. There is therefore quite a wide

variation in hydrophobicity between different classes of steroids and within these classes, which can be further modified by conjugation. Most steroids are neutral but the phenolic A ring of the oestrogens and the C₂₄-carboxyl in the bile acids render them acidic and this property can be used for the differential extraction of these two classes of steroids.

In any analytical system there are three interdependent steps: extraction (removal of the analyte from the matrix), separation of the analyte from other compounds, which may interfere in the final step – quantitation. Separation and quantitation are clearly very closely linked in that a quantitation procedure of high specificity may well not require such intensive separation as would be required with a low specificity quantitation. Because of the chemical similarity of the many steroids with each other and, in general, the lack of highly specific quantitation procedures, separation of steroids prior to quantitation is still extremely important. Each of these three stages will be dealt with individually but it must be remembered that, when an analytical procedure is being put together, one stage cannot be viewed in isolation from the others.

Extraction

Unconjugated steroids are hydrophobic and are relatively easy to extract from the aqueous matrices in which they are often found. The apparent dichotomy of hydrophobicity and the presence of unconjugated steroid hormones in human plasma is resolved when one recognizes the presence of specific binding globulins. The main glucocorticoid, cortisol, has a specific binding globulin (transcortin) and the sex hormones also have a specific globulin which transport these steroids in human blood. To extract steroids therefore from serum or plasma, it is necessary to disrupt the steroid–protein binding. Some steroids, such as cholesterol or vitamin D₃, are particularly difficult to extract and it is thought that this occurs because they become involved in lipoprotein structure. It is possible to overcome this difficulty by extracting with ethanol–ammonium sulfate or pentylamine. Most steroids however can be extracted from plasma/serum or incubation medium with a simple Bligh & Dyer extraction which utilizes methanol–chloroform (2 : 1, v/v). A simple wash of the organic extract with alkaline buffer will remove fatty acids which are also extracted but may interfere in subsequent analysis. However, washing with alkaline buffer may also remove substantial quantities of acidic steroids such as bile acids and oestrogens. In the past, ether was a common solvent for steroid extraction as it is less dense than water and the

aqueous layer can be frozen with solid CO₂ and the organic extract poured off. However, in more safety-conscious times, the flammability of ether has reduced its use.

The extraction of steroids using solvents is discussed in more detail in texts cited in the Further Reading section. Such procedures should not be viewed solely as a means of extraction as judicious choice of solvents can give a surprising degree of selectivity and particular steroid groups can be preferentially extracted. Steroid conjugates, which are more difficult to remove from aqueous media, can also be extracted from, for example, human urine using ether-isopropanol after saturation of the urine with ammonium sulfate—so-called forced extraction. The conjugates can then be hydrolysed using enzymes (β -glucuronidase or sulfatase) or, in the case of sulfate, acid solvolysis can be utilized. The need for hydrolysis of steroid conjugates depends upon the subsequent separation and quantitation techniques. Clearly hydrolysis of conjugates loses information which may or may not be of importance. As will be seen later, modern methods of analysis using LC-mass spectrometry (LC-MS) allow for the separation and quantitation of intact conjugates and it may therefore be unnecessary to hydrolyse before proceeding to the separation or steps.

Solvent extraction leads to the generation of relatively large volumes of potentially hazardous solvents which need to be removed, usually using a rotary evaporator or simply blowing nitrogen onto the solvent while heating it not higher than about 40°C. Solvents which have high boiling points or solvent mixtures containing water are particularly difficult to remove. Because of these problems, other methods of extraction have been investigated and, in the case of steroids, major advances have been made, particularly in the field of solid-phase and immunoaffinity extraction. As examples of solid-phase extraction (SPE), one can consider the use of microparticulate silica for the extraction of steroids and vitamin D metabolites. There are a wide variety of such materials which are all based upon microparticulate silica, modified by derivatizing the polar groups with silanes (i.e. octadecylsilane (ODS) C₁₈, is widely used). Structures and performance of the solid-phase materials can most readily be obtained by looking at the catalogues of manufacturers of these materials. In the UK a very useful source of information is the catalogue of International Sorbent Technology, a major supplier of such materials (e.g. Bond-Elut). Sep-Pak is another useful proprietary brand, manufactured and marketed by Waters. As an example of the use of these materials, vitamin D₃ metabolites in plasma, although not vitamin D₃ itself, can be extrac-

ted with acetonitrile, which disrupts the protein binding. After centrifugation to remove the precipitated protein, the extract is then poured through an ODS-silica column or cartridge (Sep-Pak C₁₈ or Bond-Elut C₁₈) and the metabolites of interest can be eluted, after washing, with methanol. A similar procedure can be used for other steroids in plasma or urine and often their conjugates as well.

SPE techniques for steroid extraction, although not specific, are increasingly used in preference to solvent extraction. The SPE material can often be reused many times, if satisfactory washing procedures are applied between each use. Highly specific extraction can be achieved using immunoaffinity columns where antibodies to specific steroids or groups of steroids are immobilized by linking to Sepharose. Aqueous mixtures of steroids can then be passed down the column: steroids of interest are bound to the antibody and after the unwanted steroids have passed through the column the steroid antibody binding can be disrupted and the steroid(s) of interest eluted. In ideal cases using highly specific antibodies and a relatively specific quantitation, it may not be necessary to carry out any further separation procedures. Sometimes simple procedures can be extremely effective. As an example, the binding of some plasma steroids to specific globulins can allow selective extraction as ammonium sulfate can sometimes be used to precipitate the specific globulin, which brings the steroid of interest with it.

Separation

Today high performance liquid chromatography (HPLC) is widely used for steroid separation because this technique can be directly linked to quantitation. This is, however, not to imply that other methods of separation may not find use in particular applications. Open-column chromatography (either adsorption or partition) is still used with advantage on occasions. A major and very useful separatory technique is TLC and, if microparticulate material is used, it becomes high performance TLC (HPTLC). TLC is particularly advantageous in that numbers of separations can be carried out at the same time and the apparatus required is inexpensive. For these reasons and because TLC is relatively easy to carry out, it is still quite widely used and scrutiny of recent papers on steroid separation confirms this. It is however true to say that very little development of TLC systems has occurred in the last 20 years and most systems are based upon methods described prior to 1980. TLC can also be used as a preliminary means of investigating new solvent systems for the separation of steroids by HPLC.

Column Chromatography

This procedure utilizes adsorbent materials such as alumina, Florisil (magnesium silicate) or silica. Steroids are adsorbed to these materials and are eluted by solvents of increasing polarity. The order of elution depends upon the solvent and the differing polarity of the steroids under consideration. Clearly, the more polar a steroid (in general, this means the more hydroxyls it contains), the more hydrophilic the steroid becomes and the longer it takes to be eluted. These adsorbent materials are usually packed into small columns (for example, Pasteur pipettes can be used) and exquisite separations can now be achieved by the use of microparticulate silica. These columns are simple to use, provide rapid separations and have the advantage that after washing they can be reused many times. Classical steroid separations using columns can be achieved by partition chromatography using biphasic solvent systems. The stationary aqueous phase is mixed with celite (a diatomaceous earth) and this material is packed into the column; the steroid mixture is applied and eluted with the organic mobile phase. This is rather a cumbersome procedure but does offer a considerable degree of separation. It is not widely used today, although examples of partition chromatography used in this way can still be found. An example of this technique for the separation of some progesterone metabolites is illustrated in Figure 2.

Modified cross-linked dextran columns (i.e. Lipidex) have been used to provide steroid separations and can find more mundane uses such as the removal of excess trimethylsilylimidazole reagent when forming steroid trimethylsilyl ethers. A similar material, Sephadex LH-20, has also been used to fractionate steroids into free steroids, glucuronides, mono- and disulfates. Sephadex can also be modified by linking it to form, for example, diethylaminoethyl-substituted material which can act as an ion exchanger as well as a size exclusion material. These ion exchange/gel filtration columns are particularly useful for the separation of steroid conjugates; for example, bile acids can be separated by the use of another modified Sephadex, PHP-LH20. Figure 3 shows such a system for the separation of steroids and their conjugates from human urine prior to gas chromatography-MS (GC-MS).

Thin-Layer Chromatography

TLC is in effect very similar to column chromatography and is based on the same principles. A thin layer of adsorbent or inert material is spread on a glass, plastic, or aluminium sheet. For the separation of steroids using organic solvents, the use of thin layers on plastic sheets is not recommended and either glass or aluminium should be used. After separation, steroids may be recovered from the plate by scraping off the thin layer and eluting the steroid of interest.

Figure 2 Chromatogram of selected C_{21} steroids in urine. Radiolabelled and nonradiolabelled authentic steroid standards were applied to a 40 g column of celite-propylene glycol and eluted with iso-octane (e.g. Iso-8, 40 fractions) and thence a linear gradient of iso-octane-ethyl acetate (e.g. Iso-8, 140 fractions). Steroids are identified as follows: 5α DHP, 5α -pregnane-3,20-dione; $5\alpha3\alpha$, 5α -pregnan-3 α -ol-20-one; $5\alpha20\alpha$, 5α -pregnan-20 α -ol-3-one; $5\alpha3\beta$, 5α -pregnan-3 β -ol-20-one; 20α DHP, Δ^4 -pregnen-20 α -ol-3,20-dione; DOC, Δ^4 -pregnen-21-ol-3,20-dione; 6β OH-P, Δ^4 -pregnen-6 β -ol-3,20-dione; 21 OH-P5, Δ^5 -pregnen-3 β ,21-diol-20-one. (Reproduced with permission from Dombroski RA, Casey ML and MacDonald PC (1997) *Journal of Steroid Biochemistry* 63: 155-163.)

Figure 3 Use of solid-phase extraction and Sephadex-based packing materials for the extraction and separation of steroids and their glucuronide, sulfate and *N*-acetylglucosaminide conjugates from human pregnancy urine prior to analysis by gas chromatography–mass spectrometry (GC-MS). (Reproduced with permission from Meng LJ, Griffiths WJ and Sjövall J (1996) *Journal of Steroid Biochemistry and Molecular Biology* 58: 585–598.)

The advantage of thin layers on aluminium foil is that the area of interest can be cut out and the whole area of the plate can be eluted without removing the adsorbent.

The commonest forms of TLC for the separation of steroids use adsorbent thin layers of either alumina or silica gel, although there are descriptions of reversed-

phase partition TLC. Use of microparticulate silica (HPTLC) confers a slightly enhanced selectivity in separation but HPTLC is not widely used. The steroid extract of interest is applied to the bottom of the plate and eluted with various solvents. Because of the ability of such separation systems to deal with a number of separations at once, they are still quite widely used

today. The vast majority of separation systems use silica gel but alumina has been used to separate C₁₉ androgens. The resolution is achieved by judicious choice of solvents as the number of adsorbents available is limited.

Very little development of this separation technique for steroids has been carried out over the last 20 years as attention has been diverted towards the development of HPLC. Recent TLC systems using silica gel and eluting with ethyl acetate: petroleum ether have enabled hydroxylated metabolites of progesterone to be resolved and again using silica gel with benzene–heptane–ethyl acetate or chloroform–ethyl acetate has enabled resolution of catechol oestrogens. In many instances, however, suitable solvents can no longer be used as they pose unacceptable risks of flammability or toxicity (e.g. benzene). A study of papers published in the last 10 years involving the use of TLC for the separation of steroid metabolites indicates that most procedures were published many years ago, although the recent use of cyclo-

dextrin in the TLC of bile acids (cyclodextrin in the mobile phase) and steroidal drugs (cyclodextrin polymer-coated silica) has been an interesting innovation.

Table 1 lists some examples of the recent use of TLC for the separation of steroids and clearly illustrates the increasing reliance on silica gel as the adsorbent, using the differing polarity of the elution solvent mixture for resolution. Most of the development systems are modifications of previously published solvent mixtures. Table 1 also illustrates the use of two-dimensional TLC and multiple development in the same direction. It is also possible to utilize one solvent mixture for de-fatting, followed by another to separate the steroids of interest or sequential solvent systems, separating first one group of steroids followed by a second solvent mixture to separate another steroid group.

The problem associated with the use of TLC for the separation of steroids is to locate the position of the steroids after chromatography and some methods

Table 1 Some examples of recent use of TLC for steroid separation

<i>Steroids</i>	<i>Adsorbent</i>	<i>Development solvent</i>	<i>Detection</i>
Side chain cleavage products of ¹⁴ C-cholesterol	Silica gel G	Di-isopropyl ether–hexane–acetic acid (70 : 30 : 2)	Radioactivity by autoradiography
Metabolites of 7 α -OH-androstene-3,17-dione	Silica gel	Ethyl acetate–hexane (3 : 7)	
7-Hydroxylated DHEA	Silica gel F254	Ethyl acetate	UV absorption

Metabolites of ³ H-progesterone, -pregnenolone and -DHA	Fisher silica gel 60 F254	Two-dimensional TLC firstly to de-fat in cyclohexane–ethyl acetate (95 : 5) \times 5–7. Then toluene–acetone (8 : 2) \times 2, finally \times 2 in first direction with cyclohexane–ethyl acetate (1 : 1)	Autoradiography

used for this purpose are also summarized in Table 1. For steroids containing UV-absorbing groups, such as the δ -4-3-oxo group in the A-ring of most active steroid hormones and the aromatic ring in the oestrogens, visualization can be achieved by examining the plate under UV light. To improve the detection of steroids absorbing at around 240 nm, most commercially available TLC plates have a fluorescent material incorporated which improves detection of the absorption of UV light at around 254 nm. Other techniques are often destructive and require reagents to be sprayed on to the plate. Thus, to avoid destroying the steroid of interest, it is necessary to have standards run on the same plate at the side so that the position of the steroids of interest can be gauged. There are other nondestructive means of visualization, such as the use of iodine vapour but these are not always satisfactory, particularly at low concentrations. One advantage of TLC is in the separation of radiolabelled steroids which can be visualized by autoradiography.

High Performance Liquid Chromatography

The application of HPLC to the separation of steroids has been extensively studied over the last 20 years. A detailed and comprehensive review of the HPLC of steroid hormones was published in 1988 and updated in 1995 (see Further Reading). HPLC is in essence no different to the column and thin-layer systems discussed above, although the resolving power of modern HPLC columns is significantly greater: some reversed-phase columns achieving 60 000–80 000 theoretical plates per metre. New solvent systems for normal-phase HPLC can be investigated using TLC. Columns, because of the high resolving power which can now be achieved, are usually quite short (100–300 mm long with an internal diameter of 4.6 mm). Microbore columns (< 2 mm in diameter) can be used to reduce mobile phase consumption but may present practical problems because of the limitation in sample capacity. However, microbore columns may have considerable application in LC-MS, because of the low solvent flow rates. Silica contains free OH groups and these can be modified, replacing the OH for example with cyanopropyl (CN, used for the separation of corticosteroids) or aminopropyl (NH_2 , used for the separation of oestrogens). Improved resolution of particular steroids can sometimes be achieved using these modified silicas and, for example, silica-CN gives selective retention of steroids containing oxo groups, and has been particularly useful in the separation of the 25-hydroxyvitamin D_3 -23,26-lactone which is difficult to resolve from 24,25-dihydroxyvitamin D_3 in conventional normal-phase HPLC systems. Reversed-phase HPLC is usu-

ally based on silica modified with silanes of various chain lengths – C_{18} (ODS) silica is the most widely used material for this purpose. Column packings based on synthetic material are now being made available and may in the future replace silica. Considerable advances in the production and quality of these packing materials have been made over the past 10 years and thus reproducibility of separations has improved.

Most steroid separations today use reversed-phase systems with C_{18} or C_8 silica, although an exception to this general rule is the separation of metabolites of vitamin D which use normal-phase systems eluting with hexane–isopropanol–methanol or hexane–methanol–chloroform. Binary hexane–isopropanol systems give significant tailing and resolution problems which are improved by the use of ternary solvent mixtures. These normal-phase systems give excellent resolution of the metabolites of vitamins D_2 and D_3 but do not separate the vitamins themselves (Figure 4), which can be achieved using reversed-phase ODS–silica eluting with methanol–water. If steroids are to be recovered from the eluting solvent, it is clearly advantageous if normal-phase systems with sufficient resolving power can be developed as the removal of aqueous solvents used in

Figure 4 LC separation of vitamins D_2 and D_3 , 24-OH- D_2 , 24-OH- D_3 , 25-OH- D_2 and 25-OH- D_3 , using Zorbax-SIL and eluting with 2.5% isopropanol in hexane. (Reproduced with permission from Jones G and DeLuca HF (1975) *Journal of Lipid Research* 16: 448–453. Copyright 1975 FASEB.)

Table 2 Examples of some recent HPLC systems for the separation of steroid hormones and bile acids

<i>Steroid group</i>	<i>Carbon atoms</i>	<i>Stationary phase</i>	<i>Mobile phase</i>	<i>Comments</i>
Vitamin D	C ₂₇ (D ₃ series)	Zorbax ODS	MeOH (MeCN)-H ₂ O (acid)	Separation of D ₃ and D ₂
Secosteroids	C ₂₈ (D ₂ series)	Zorbax CN Zorbax SIL	Hx-IPA-MeOH Hx-IPA-MeOH	Retards metabolites containing oxo groups Usual system for metabolite resolution
Bile acids	C ₂₄	YMC GEL C8 Bile Pak II	MeCN-H ₂ O + cyclodextrin Gradient with MeCN-MeOH-PO ₄ buffer	Bile acids and their conjugates as bromopyrenacyl esters Bile acid conjugates using post-column immobilized 3 α OHSDH and fluorescence detection

Androgens	C ₁₉	NovaPak C ₁₈ Hypersil BDS-C ₈ Hibar Lichrosorb-DIOL	Gradient of MeCN-H ₂ O Gradient of 7.5 mmol L ⁻¹ NH ₄ Ac-MeOH Hx-IPA	DHEA and 7-OH-DHA in newborn foal's blood LC-MS of testo. and epi-testo. glucuronides/sulfates Metabolites of DHT and androstanediol
Oestrogens	C ₁₈	Wakosil C ₁₈ Beckman ODS	MeOH-H ₂ O MeCN-H ₂ O + cyclodextrin	Plasma oestrogens-pre-column derivatization as benzimidazoles Urinary oestrogens

reversed-phase separations causes considerable difficulties. Corticosteroids have been successfully separated using normal-phase systems based on DIOL-silica sorbents (-Si-2,3-dihydroxypropoxypropyl) and ion exchange HPLC has also been used for the separation of polar oestrogens. Some recent examples of typical HPLC systems used for the separation of steroids are given in Table 2, which illustrates the fact that most methods in use today are reversed-phase systems using ODS/C₁₈ packings.

All steroids are susceptible to permanent absorption and/or chemical destruction or modification by unsilanized glass surfaces, exposed metal and by non-inert supports and, for quantitative HPLC, great care must be taken to remove or reduce such materials. Sorbents containing accessible hydroxyl groups should not be used for the separation of 18-hydroxylated steroids as chemical modification of these steroids may occur during chromatography. Although not relevant to HPLC, it should be pointed out that partially end-capped ODS-silica can still be used with advantage in particular situations for rapid separations after SPE. As an example, the use of Bond-Elut C₁₈-OH allowed both extraction and subsequent separation on the same cartridge in a method for the assay of calcitriol (1,25-dihydroxyvitamin D₃).

One particular advantage of HPLC is that it is not destructive and can thus be used for the separation and quantitation of intact steroid conjugates. These

polar molecules are not susceptible to analysis by GC as the high temperature necessary to maintain steroids in the vapour phase causes hydrolysis of the conjugate. Examples of the application of HPLC to the separation of androgen and oestrogen glucuronides and the application of LC-MS(MS) to the separation of intact conjugates and steroid fatty acid esters are given in the Further Reading section. An example of such a separation is given in Figure 5. Until the advent of HPLC, steroid conjugates had to be hydrolysed prior to resolution and important information was thus lost. The use of LC, particularly when coupled to MS(MS), has allowed resolution and quantitation of intact conjugates together with structural information. HPLC systems for steroid conjugates are usually but not exclusively reversed-phase primarily based on ODS-silica eluting with methanol-, tetrahydrofuran-, acetonitrile-water or buffer solvent systems. The conjugates can be detected in the same way as nonconjugated steroids and this is discussed below.

Detection/Quantitation

This is the final and perhaps most important step and there are a variety of methods which can be used for the detection or quantitation of steroids. These methods are usually considered only in conjunction with HPLC as they are usually insufficiently specific

Figure 5 Analysis of maternal urine for the detection of placental sulfatase deficiency (PSD). The microbore HPLC-ES-MS chromatograms represent selected ions for detection of pregnanediol glucuronide, oestriol glucuronide and 16 α -hydroxy-DHEA sulfate. The selected-ion chromatograms on the left of the figure are from a normal individual and those on the right are from a patient with PSD. Oestriol and its glucuronide cannot be synthesized by women with PSD, and the precursor 16 α -hydroxy-DHEA sulfate is a dominant steroid in urine. The amount injected into the microbore column was equivalent to 25 μ L of urine, the eluate being split 10 : 1 prior to the mass spectrometer. The column used was a Reliasil number 9, 1 \times 100 mm. Solvent A was 98% 10 mmol L⁻¹ ammonium acetate in H₂O, 2% acetonitrile; solvent B was 100% acetonitrile. The gradient was 2% B to 30% over 20 min, and a flow rate of 40 μ L min⁻¹ was used. From Makin HLJ, Gower DB and Kirk DN (eds) *Steroid Analysis* (1995) Reproduced with permission from Kluwer Academic Publishers.

to be used without rigorous prior separation of interfering steroids – the exception to this being immunoassay which can, depending upon the antibody, be sufficiently selective and sensitive for use directly on plasma/serum without extraction or prior purification. There are a number of such assays available today but their uncritical use can lead to problems. An example of this is an immunoassay for 17-hydroxyprogesterone, developed for use with adults. This was applied to the diagnosis of a genetic defect in cortisol biosynthesis, congenital adrenal hyperplasia. The possible interference in this assay by 17-hydroxypregnenolone sulfate which is normally produced in very young children was not appreciated. A simple solvent extraction procedure overcame this problem once it was detected.

It is often the case that one or other of the simple purification procedures, such as selective solvent extraction, use of mini-columns or even TLC on small plates can greatly enhance specificity and there are many examples of this in the literature. It is often unnecessary to use expensive HPLC systems to resolve these steroid analytical problems and consideration of the physicochemical properties of the steroid of interest may often suggest a simple non-HPLC solution. Immunoassay is however one of the most sensitive methods of steroid quantitation and, coupled with HPLC, even with a relatively non-specific antibody, can provide a system with both high specificity and sensitivity. It does however require collection of the eluent – so called offline detection.

Figure 7 Use of photodiode array detection in HPLC separation of metabolites of 25-hydroxydihydrocholesterol₃. Monitoring the eluent at 251 nm indicates what appears to be a single homogeneous peak. Examination of the UV spectra at the leading edge, the apex and the trailing edge clearly demonstrates the presence of a contaminant. From Makin HLJ, Gower DB and Kirk DN (eds) *Steroid Analysis* (1995). With permission from Kluwer Academic Publishers.

Other detection methods can be used, such as UV absorption with or without derivatization, fluorimetry after chemical modification or derivatization or electrochemical detection. These detection/ quantitation methods can usually be carried out online – that is to say, that the HPLC eluent can be directly and continuously monitored. When chemical derivatization is required, this can be carried out prior to HPLC (pre-column derivatization) but this may reduce resolution. In such cases it is also possible to carry out the derivatization after the HPLC separation (post-column derivatization). Some examples of pre-column derivatization used for fluorescent detection are illustrated in Figure 6.

One particular method of UV monitoring of eluents from HPLC separations is the photodiode array detector. With this detector the absorption of the eluent is continuously monitored over a range of wavelengths and the data stored in a computer. Reconstructed chromatograms can be obtained at a later date, as can three-dimensional reconstructions (showing time versus absorbance versus wavelength). An example of photodiode array detection is illustrated in Figure 7, which demonstrates that what appears to be a single peak when monitored at 251 nm is in fact composed of two unresolved compounds and this can be demonstrated by comparing the UV spectra obtained at the leading edge, the apex and the trailing edge of the peak. This lack of resolution is also seen in the three-dimensional picture. This particular separation was obtained when examining the metabolites of a chemical analogue of 25-hydroxyvitamin D.

HPLC can also be linked to mass spectrometry and, increasingly, techniques are becoming available for the direct linking of the column to the mass spectrometer. In the past, mass spectrometry of HPLC eluents had, like immunoassay, required that eluents be collected and prepared for mass spectrometry. The availability of ionization techniques (such as atmospheric pressure ionization, electrospray, etc.) now allow the HPLC eluent to go directly to the mass spectrometer. Many steroids are susceptible to ionization in such systems but others require derivatization to achieve satisfactory ionization. In these systems the elution solvents should contain water or salts, which implies the use of reversed-phase separation. This is not a particular problem with most steroids but for particular steroid groups (e.g. metabolites of vitamin D) it may require the development of new solvent systems. Such ionization procedures are inevitably low energy and fragmentation is limited. The advantage of this low energy ionization is that intact steroid conjugates can be examined. However, low energy ionization is inefficient, limits the sensitivity of detec-

tion and does not yield information about structure. To some degree this structural limitation can be resolved by utilizing LC-MS-MS where the first mass spectrometer allows only the major ion obtained to pass through to a collision cell. Here the ion is subjected to higher energy ionization or bombardment, producing further fragments which can then be analysed by a second mass spectrometer, yielding structural information. Such systems are expensive but are immensely valuable. Unfortunately, LC-MS and LC-MS-MS are not as sensitive as GC-MS, which has been widely used for the measurement of many steroids present at low concentrations in human body fluids. High resolution GC-MS can of course increase sensitivity of detection even further.

Conclusion

The advent of simpler and cheaper mass spectrometers which allow direct coupling of the LC column has meant that less attention needs to be paid to resolution and the development of solvent systems and column packings to achieve improved resolution is no longer as important. Attention has therefore shifted towards increasing sensitivity by the use of microbore columns with the low flow rates required for maximum ionization in the MS and the use of nanospray ESI. Today excellent mass spectra can be obtained using such systems with femtomole concentrations of analyte. There is considerable scope for further enhancement of sensitivity and selectivity by improved MS design of both hardware and software.

Supercritical Fluid Chromatography

Supercritical fluid chromatography (SFC) has been recognized as a powerful separation technique complementing gas chromatography (GC) and high performance liquid chromatography (HPLC). Klesper *et al.* published results of the use of supercritical dichlorodifluoromethane and monochlorodifluoromethane to separate involatile nickel porphyrin in 1961. The development of the technique was limited by instrumental and experimental difficulties due to the high temperatures and pressures required to maintain the mobile phase in a supercritical state. Novotny and Lee, however, developed SFC with a capillary column (cSFC) in 1981, which led to significant advances in the technique. In 1982 Gere *et al.* developed an instrument for packed-column SFC (pSFC) based on modification of an HPLC. They demonstrated, using polycyclic aromatic hydrocarbons as probe molecules, that the resolution per unit time in pSFC was 5–10 times better than in HPLC with the same columns, due to more favourable diffusivity in supercritical fluids.

The advantages of SFC have been described elsewhere in this *Encyclopedia*. Pure carbon dioxide fluid is a solvent of inadequate polarity. For the analysis of polar compounds by SFC, alcohol is generally added to a mobile-phase fluid as a modifier. Small amounts of polar modifiers significantly increase the solvent strength of the mobile phase and make it possible to elute polar compounds. In particular, pSFC has been applied to various kinds of polar compounds such as drugs, and shown to be superior to HPLC with respect to analysis time, efficiency and selectivity.

The nonpolar steroids cholesterol and ketosteroids are easily eluted by either cSFC or pSFC with pure carbon dioxide. Synthetic corticosteroids, which are widely used therapeutically for the suppression of

adrenocortical functions, inflammatory and allergic diseases, have multiple hydroxyl functional groups in the structures. In order to modify the efficacy and suppress adverse reactions, many corticosteroids have been synthesized. Thin-layer, normal and reversed-phase chromatography have been used for the analysis of these compounds. For a number of the synthetic corticosteroids used in therapy, very little work has been carried out by pSFC. These polar steroids are probably difficult to elute with pure carbon dioxide due to its poor solvent strength.

In this article, the pSFC retention behaviour of synthetic corticosteroids, possessing one to four hydroxyl groups, are focused on. The effect of several parameters (stationary phase, modifiers, pressure and temperature) on retention and efficiency are considered. The chemical structures of corticosteroids are shown in **Figure 1**. They were chromatographed using a pSFC instrument modified from a commercial HPLC system. The addition of methanol to carbon dioxide and adoption of an aminopropyl stationary phase produced both good resolution and symmetric peak shapes. Both plate number and resolution indicated that the maxima were around the critical temperature (40–50°C) of the binary fluid. The selectivity and separation of the analytes in pSFC are superior to those in existing normal and reversed-phase HPLC. Seven polar corticosteroids, possessing one to four hydroxyl groups, showed baseline separation within 6.5 min with a modifier gradient method.

Instrumentation of pSFC

Most studies have been done using commercial pSFC instruments. However, a pSFC with the same performance as a commercial instrument can easily be constructed. The HPLC for pSFC operation requires some simple adaptations to allow use of supercritical carbon dioxide as a mobile phase. The pSFC system constructed by the authors by modifying a Shimadzu HPLC is shown in **Figure 2**.

Figure 1 Structures and symbols of synthetic corticosteroids.

Effect of Analytical Parameters

Stationary Phase

Peak shapes of polar solutes on a packed column are often poor when pure carbon dioxide is used as the mobile phase. The separation of steroids has been performed using columns with phenyl, nitrophenyl, diol, aminopropyl, octadecyl and cyanopropyl-modified silica and pure silica as packing materials. It is likely that only polar modifiers used with polar stationary phases produce both good resolution and symmetrical peaks. As shown in **Figure 3**, an aminopropyl column exhibited the best selectivity and peak shape with a reasonable retention time in comparison with the others. Octadecyl and phenyl columns showed poor separation: the former did not retain any solutes and the latter did not separate under the operating conditions used. On the silica support, the solutes showed appropriate retention but poor separation and peak shape. Although the retention times of triamcinolone acetonide, fluocinolone acetonide, hydrocortisone and betamethasone were almost the

same as those on the aminopropyl column, the separation factor, α , of the two pairs – steroids possessing two hydroxyl groups, and steroids possessing three hydroxyl groups – decreased remarkably on silica. A reversed elution order, however, was observed on the silica, which showed that it is possible to change selectivity by selecting the stationary phase.

Modifier

In pSFC, the addition of a modifier to a mobile phase should be considered from the viewpoint of its effect on either the stationary phase or on the mobile phase. Berger *et al.* have studied the effect of column and mobile-phase polarity using steroids. They concluded that polar modifiers tended to decrease the intensity of the solute–silanol interaction, and more polar stationary phases produced greater retention, requiring the use of modifiers to obtain reasonable retention times. Blilie and Greibrokk indicated that the modifiers functioned as deactivation agents by direct interactions with residual silanol groups, and also as modifiers of the eluting power of the mobile phase.

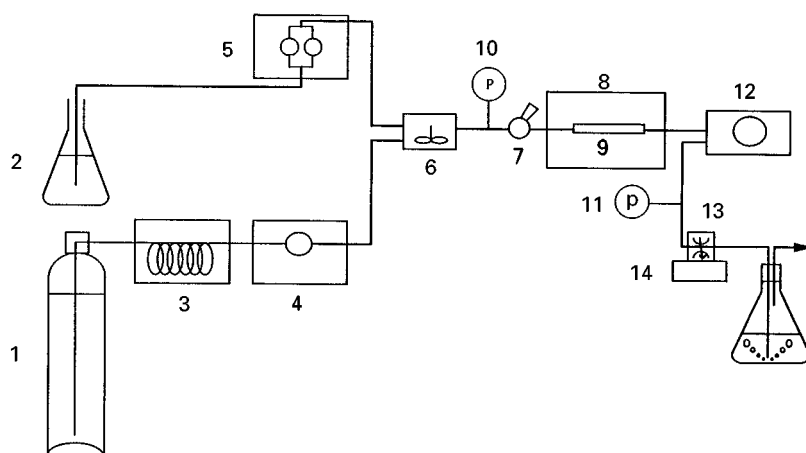

Figure 2 Schematic diagram of packed-column supercritical fluid chromatography. 1, Carbon dioxide cylinder; 2, modifier; 3, cooling bath; 4, LC-6A pump; 5, LC-9A pump; 6, dynamic mixer; 7, injector; 8, oven; 9, packed column; 10 and 11, pressure monitor; 12, detector; 13, back-pressure regulator; 14, dry thermo unit.

No corticosteroids were eluted from the column packed with Cosmosil 5NH₂ with pure carbon dioxide as the mobile phase and a modifier had to be added. The effect of modifiers with different polarities on the retention of corticosteroids is shown in **Figure 4**. The addition of 11.8% (v/v) methanol to carbon dioxide gives the best resolution and symmetrical peak shapes within 14 min. In comparison, the addition of the same amount of 99.5% ethanol, and of 95% ethanol reduced resolution but remarkably improved the peak shape of the most polar compound, triamcinolone, in the corticosteroids. This should be attributed to deactivation of the active sites on the silica support by the water in the 95% ethanol.

Janssen *et al.* confirmed that the effect of a few per cent of modifier in pSFC is largely due to deactivation

of residual silanol groups on the silica support, and the accessibility to the active sites depends strongly on the size and structure of the modifier molecules. According to Janssen *et al.*, the same volume percentage of tetrahydrofuran (THF) and methanol was needed to cover 95% of the surface, but since no corticosteroid was eluted under these conditions when methanol was replaced with THF, the effect of the modifier on retention of corticosteroids consists in the enhancement of the solvent strength of the mobile phase rather than deactivation of the active sites on the silica support.

The capacity factor of every corticosteroid decreased two- to fourfold with a 1.8-fold increase in methanol concentrations over the range 9.1–16.7% v/v. All solutes were eluted within 5 min using carbon

dioxide modified with 16.7% (v/v), and the resolutions among them were more than 1.6.

Calculated relative standard deviations (RSD) of 0.35–0.70% for t_R , 0.82–1.47% for k and 0.50–1.34% for peak area are shown in Table 1, indicate that the pSFC modified from a commercial HPLC system has a good performance and is useful for a routine analysis.

Pressure

In a study of seven corticosteroids, the capacity factor of each solute decreased by a factor of two with an increase in the range of 107–223 kg cm⁻². A few researchers have measured the densities of modified supercritical fluids experimentally. Berger measured the density of binary fluids using a U tube densitometer and drew the constant density lines in plots of the pressure against the composition for methanol–carbon dioxide system at three temperatures. The densities of CO₂–methanol (12%, v/v) at different pressures can be calculated by extrapolating the lines in the pressure range 105–180 bar. The plots of $\ln k$ against the binary fluid density revealed that there is a linear relationship between them in SFC, as expected.

Except for fluocinonide, theoretical plate numbers (N) reached maximum values at 126 and 144 kg cm⁻², as shown in Figure 5. The maximum N values were *c.* 4700–9800. Corresponding to the behaviour of the N values, the resolutions between the adjacent solutes also showed a maximum at 126–162 kg cm⁻². Since the mass flow rate was kept constant, the linear velocity varied with pressure. The minimum plate height was obtained in this pressure range. These results reveal that pressure is one of the significant parameters for optimizing the operating conditions.

Temperature

The retention of corticosteroids increases with an increase in the temperature (decrease in the density). The N values of each solute also increase with temperature as shown in Figure 6, and reach maximum values at 39 or 49°C, with the exception of hydrocortisone. The maximum N value for triamcinolone is *c.* 8400 at 39°C but only *c.* 3200 at 58°C, corresponding to about a 60% decrease. Although little variation in the separation factor (α) of any pair of neighbouring solutes was observed over the wide range of temperature measured, resolution reached maximum values at 39–49°C, corresponding to the behaviour of the N values. The critical temperature and pressure

Table 1 Repeatability (RSD%, $n = 6$)

Corticosteroids	t_R (min)	k	Peak area
Fluocinonide	0.37	1.15	1.01
Dexamethasone acetate	0.35	1.10	0.75
Triamcinolone acetonide	0.49	1.39	1.08
Fluocinolone acetonide	0.60	1.47	1.34
Hydrocortisone	0.64	1.39	0.67
Betamethasone	0.70	1.39	1.09
Triamcinolone	0.45	0.82	0.50

Operating conditions as in Figure 3.

Figure 5 Relationship between theoretical plate numbers and pressure. Operating conditions: mean pressure 107, 126, 144, 162, 184, 205 and 223 kg cm⁻²; other conditions as in Figure 4. Symbols: squares, hydrocortisone; diamonds, fluocinolone acetate; circles, betamethasone; triangles, triamcinolone.

were reported to be 36.85°C and 80 bar and 50°C and 95 bar for 2% methanol and 16% methanol in carbon dioxide, respectively. So, the critical temperature for 12% methanol in carbon dioxide, which we used as the mobile phase, can be assumed to be in the range of 40–50°C: the maximum

Figure 6 Relationship between theoretical plate numbers and temperature. Operating conditions: temperature 22, 29, 39, 49 and 58°C, mean pressure 213 kg cm⁻², other conditions as in Figure 4. N and resolution were obtained around the critical temperature.

Separation with Modifier Gradient

A wide range of polar corticosteroids has been separated in a modifier gradient elution mode. As shown in Figure 7, all solutes were eluted within 6.5 min by increasing the methanol content from 11.8% (v/v) to 17.0% (v/v) at 0.52% (v/v) per min, and keeping the CO₂ flow rate constant. Good peak shapes, completely baseline separated, were observed. The stable baseline without drift and noise is considered to be due to the good mixing process of the binary fluid. In pSFC, a modifier gradient is one of the most effective techniques for the analysis of polar steroids.

Comparison with HPLC

The retention of a wide range of corticosteroids by pSFC using an aminopropyl silica column has been compared with that in normal and reversed-phase

Figure 7 Gradient elution of corticosteroids. Operating conditions: column Cosmosil 5NH₂, flow rate of CO₂ 3 mL min⁻¹, methanol gradient 11.8–17.0% (v/v) at 0.52% (v/v) per min, mean pressure 206 kg cm⁻², temperature 40°C. Peaks: as in Figure 1.

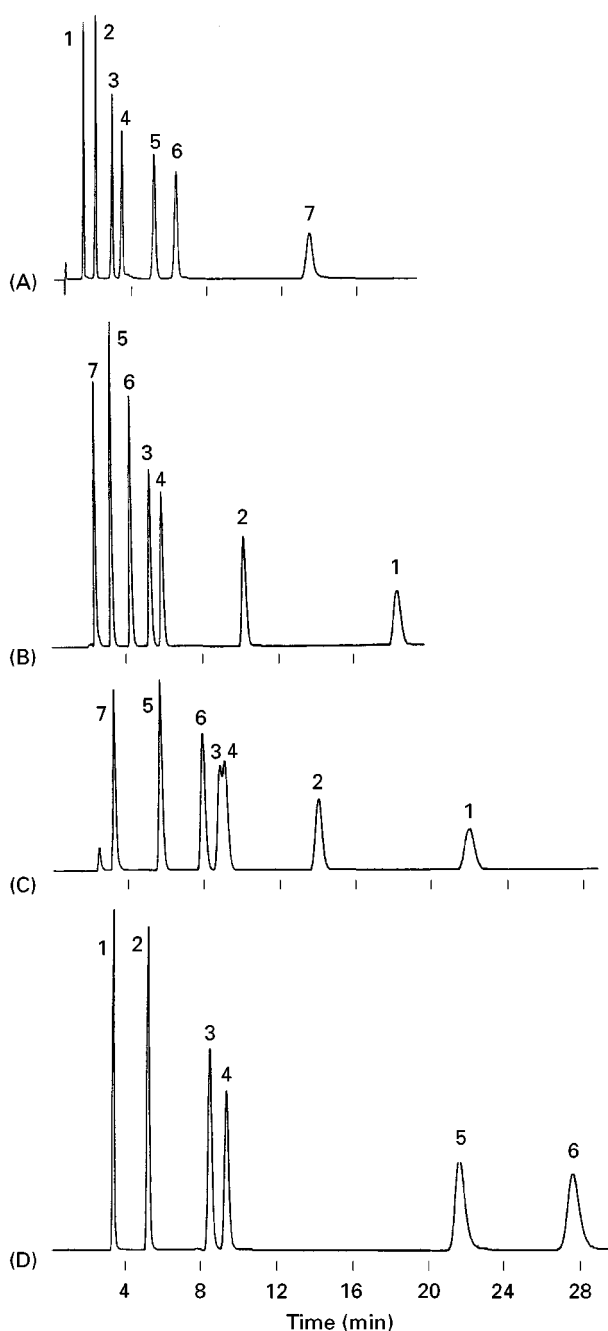

Figure 8 Chromatograms of corticosteroids. (A) Packed-column SFC; operating conditions as in Figure 3; (B) reversed-phase-HPLC (40% acetonitrile); (C) reversed-phase-HPLC (55% methanol); (D) normal-phase-HPLC. Peaks: as in Figure 1.

HPLC. The observed chromatograms are shown in Figure 8. Since the most polar corticosteroid among the analytes, triamcinolone, was not dissolved in the mobile phase, it could not be eluted in the normal-phase mode. The elution order of corticosteroids in pSFC is the same as that in normal-phase HPLC and is mainly determined by the number of hydroxyl groups present in the compound: firstly, fluocinonide with a single OH

group; dexamethasone acetate, triamcinolone acetonide and fluocinolone acetonide with two OH groups; then hydrocortisone and betamethasone with three OH groups; and finally triamcinolone, with four OH groups. Corticosteroids are eluted almost in reversed order in reversed-phase HPLC, but it is noteworthy that the pairs of triamcinolone acetonide and fluocinolone acetonide, and hydrocortisone and betamethasone are eluted in the same order as in pSFC.

The elution order of these compounds with the same number of OH groups seems to be closely related to their dipole moment. The estimated dipole moments were 1.19 and 2.04 debye for triamcinolone acetonide and fluocinolone acetonide, and 0.52 and 2.24 debye for hydrocortisone and betamethasone.

A similar range of *N* values was obtained in each chromatographic mode, i.e. *c.* 3600–8000 in pSFC, *c.* 4800–8700 in normal-phase HPLC and *c.* 2300–11 000 in reversed-phase HPLC. The separation of triamcinolone acetonide and fluocinolone acetonide, which show the lowest resolution and the same elution order in the normal- and reversed-phase systems, are comparable. The resolution of these solutes is 2.73 by pSFC, 2.04 by normal-phase HPLC, 0.53 by reversed-phase HPLC with a methanol mixture, mobile phase, and 2.20 by reversed-phase HPLC with an acetonitrile mixture, mobile phase. The elution time of all solutes in pSFC is about four times faster than in normal-phase HPLC and about 1.5 times faster than in reversed-phase HPLC.

These results suggest that the pSFC conditions used give a higher selectivity and better separation efficiency than normal-phase and reversed-phase HPLC for the analysis of corticosteroids which possess one to four hydroxyl groups.

Conclusion

PSFC is useful for the analysis of polar steroids, and its application as a rapid method for quality control and routine analysis can be expected in the future.

Introduction

In supercritical fluid chromatography (SFC) the mobile phase is a fluid subjected to pressures and temperatures near or above its critical point. This fact determines the mobile phase properties (e.g. diffusivity, density, viscosity, etc.) that are intermediate between those of gases and liquids and can be varied and controlled by small changes in the pressure or temperature. The most common fluid used in SFC is carbon dioxide, which has a critical temperature of 31°C, allowing the separation of thermally labile compounds under mild conditions. SFC can be carried out with open tubular and packed columns, with differences in selectivity, detection and need of modifier addition to the carbon dioxide. Both types have been employed in the separation of sterols in a wide variety of samples. Supercritical carbon dioxide has an adequate solvating power for sterol separation with both column types without the need of modifier addition. It is therefore possible to separate sterols in complex samples at lower temperatures than gas chromatography and in shorter times than liquid chromatography.

Importance of the Analysis of Sterols

The analysis of sterols is of great significance from the health point of view and for the quality control of numerous food products.

With respect to quality control of food and nutrition studies, the sterols of vegetable origin (phyto-

sterols) are found in complex mixtures in numerous plants, with the mixture containing some major sterols and a great variety of minor compounds (Figure 1). Thus, the sterol profile can be indicative of the origin, or species or variety of food from vascular plants, as well as from fungi or marine organisms. Additionally, these compounds are fundamental in the study of several metabolic pathways.

In the animal world, the variety of sterols is not so broad, and the main constituents are cholesterol and derivative esters. For that reason, supercritical carbon dioxide has been employed for the selective extraction of cholesterol from meat products and edible animal fats, to obtain healthier food for human intake.

On the other hand, some sterol oxides (oxysterols) are known for their toxicity, mutagenicity or carcinogenic properties, a fact that makes the determination of their concentrations in natural matrices very necessary, especially in studies of food quality and physiology.

Characteristics of the Separation of Sterols Using Supercritical Fluids

The main properties of supercritical fluid chromatography which affect sterol separation are related to the high solvating power of supercritical fluids and a low viscosity, which yields a high resolving power and rapid throughput. In addition to its other advantages, the ability of SFC to resolve complex mixtures of low volatility compounds allows the direct injection of samples that contain sterols with no or little pretreatment.

Some sterols can be degraded or lost during exposure to light, heat or extreme values of pH. In the SFC of sterols, all these factors can be avoided, providing a separation under mild conditions that preserves the integrity of the sample.

Finally, the relatively good solubility of compounds with intermediate polarity and volatility such as the sterols has also frequently been utilized in

Figure 1 Structures of the main sterols analysed by SFC.

supercritical fluid extraction (SFE) for sample fractionation of the sterols from complex matrices, creating new possibilities for the use of supercritical fluids in multidimensional systems. The solubilities and chromatographic data of the main sterols in supercritical carbon dioxide are well known, and can be found in various books and review articles (see Further Reading).

Isolation of Sterol Subclasses and Sample Preparation

The determination of the sterol fraction in complex matrices such as food provides valuable information on the quality of the product, as well as its purity, origin and plant variety. This analysis presents some difficulties owing to the complexity of the matrix and the relatively low concentration of the sterols in these samples. The most widely used method includes a solvent extraction of the lipid material and isolation of the sterolic fraction, usually after removing the triglycerides through saponification of the lipids and subsequent extraction of the unsaponifiable matter with an organic solvent.

This unsaponifiable fraction contains the sterols and other minor components, such as tocopherols,

terpenic alcohols, and hydrocarbons, and therefore often needs to be fractionated. This is conventionally performed by thin-layer chromatography or by solid-phase extraction, prior to high resolution chromatographic analysis.

When the objective is to separate many individual sterols, there is an additional fractionation of the unsaponifiable components after the extraction and sample pretreatment, to isolate the main sterol subclasses (i.e. 4,4-dimethylsterols, 4-methylsterols and 4,4-desmethylsterols, and their esters, oxides and other derivatives), and before the separation of the individual sterols of the subclass of interest. This last fractionation is usually carried out by open column liquid chromatography, thin-layer chromatography, high performance liquid chromatography or more recently supercritical fluid chromatography, after which the sterols can be injected in a gas chromatograph, with or without derivatization.

This whole procedure including saponification, extraction and fractionation is not only time consuming and error prone, and may degrade labile sterols creating artefacts. Consequently, new approaches have been developed in the last few years that avoid several or all these steps by using multidimensional systems or even direct injection into a SFC column.

SFC in Multidimensional Systems

Multidimensional systems take advantages of two different chromatographic separations with complementary characteristics, e.g. one extraction stage and one chromatographic stage. The first step is aimed at producing a clean and undiluted sample containing the fraction of interest, and the second provides a high resolution separation of the target analytes.

It is often the case in chromatography that the largest source of error in the quantitative analysis of sterols and the most time-consuming part of the analytical method is the sample preparation and extraction stage. The main advantages of online systems is that they provide a fast and easily automated sample preparation procedure which reduces or avoids many of the errors of manual extraction. Also, less solvent consumption gives reduced exposure, toxic hazards and lower disposal cost.

The online methods applied to sterol analysis have conventionally consisted in the direct coupling of normal or reversed phase liquid chromatography with capillary gas chromatography (LC-GC), which allows the isolation of the sterolic fraction by LC, followed by online transfer to the gaseous separation in a fast and effective way. An alternative approach is to use packed columns to isolate the sterolic fraction by SFC, as shown recently by Medvedovici *et al.* in 1997, who used a conventional packed column (20 cm \times 4.6 mm) with aminopropylsilica gel as stationary phase, for further analysis by capillary gas chromatography-mass spectrometry. This approach can replace the classical preparation methods, yielding a much shorter time with good reproducibility, and it can be automated.

A more interesting approach is the online coupling of SFE and SFC, that allows the transfer of the solutes from the solid matrix to the chromatograph, reducing solvent usage and the need for sample clean-up. This technique has been applied to the separation in open tubular columns of cholesterol in food, and may prove to be of great importance in the future, with the use of packed column SFC; such columns have a large sample capacity and shorter analysis time.

The use of SFC in multidimensional chromatographic systems has a number of advantages. The most common multidimensional system to date, LC-GC, is limited to the determination of thermally stable and volatile solutes, but SFC can replace either the first step (fractionation), or the second step (high resolution chromatography), or even both. In the case of SFE-SFC, the transfer is performed without changes in the mobile phase providing less risk of loss of analytes.

Direct Introduction in SFC

While the analysis of sterol esters does not present difficulties by gas chromatography, a sample preparation step is needed however to remove the fatty material, in order to minimize interferences and protect the GC system. In many cases, the advantage of SFC is that the untreated sample can be injected directly onto a packed column allowing estimation of several lipid fractions at the same time.

Another approach consists in the use of SFC either for fractionation of the oil or for direct selective analysis of the sterol composition of the sample, without previous treatment. This direct injection is a particularly promising technique, and has been applied to the analysis of oils from marine sources to obtain fingerprints of different oil compositions, taking advantage of the very simple sample preparation requirements of SFC.

Separation of Individual Sterols

For the determination of individual sterols, SFC provides the same resolution as gas chromatography and short run times, at temperatures as low as 50–80°C in packed column SFC.

A particular problem is the detection system. Simultaneous detection of many sterols is difficult with ultraviolet detection, as some of the sterols do not possess high absorptivity. Hence this detection mode must often be combined with others to provide a comprehensive detection capability. For this reason, the most usual detection systems for sterol determination are flame ionization detector (FID) or mass spectrometry, which can easily be used with either gas chromatography or SFC.

Separations of sterols have been performed by open tubular column SFC, in samples such as soybean oil derivatives or commercial antioxidant mixtures. Other compounds of interest such as tocopherols, squalene, or even di- and triglycerides can be determined simultaneously (see Table 1). (Note that Table 1 is not intended to be a comprehensive review, but aims to provide general information on selected applications.)

Although the most common method for the SFC of free sterols is to employ open tubular columns, separations of sterol-related compounds have also been achieved with columns having different packing materials, ranging from pure silica, to phenyl-, diol-, amino-, or octadecyl-modified silica. For packed columns, the peak symmetry is improved and the retention times of the sterols are shortened when a modifier is added to the mobile phase. This moderates the influence of the free silanol groups of the silica and is analogous to the end-capping of an HPLC silica-based

stationary phase. In general, the separation of the sterols in SFC is affected by parameters such as the number, location, nature and conformation of the functional groups present in the molecules.

One special case is the determination of cholesterol, which is very often performed on samples with few or no other sterols and where the main objective is to separate this analyte from other non-sterolic

lipids and minimize the sample preparation, as will be discussed below.

Determination of Cholesterol and Cholesteryl Esters

In the last few years, the relationship between plasma cholesterol levels and the risk of atherosclerosis and

coronary heart disease has been confirmed, resulting in an increase in concern about dietary and blood cholesterol levels. As a consequence, the determination of serum cholesterol is one of the most frequent clinical diagnostic measurements currently undertaken. It is usually performed after hydrolysis, quantifying the total cholesterol by routine enzymatic or colorimetric methods. In many cases, it would be more useful to separately determine free sterols and cholesteryl esters in serum to provide more complete clinical information. This analysis can be carried out by SFC at low temperature, without saponification or derivatization (see Table 2). (Again, Table 2 is not a comprehensive review but aims to provide general information on selected applications.) The determination of individual cholesteryl esters cannot be performed by the enzymatic methods available, while gas chromatography requires high temperature to elute the high-molecular-mass unsaturated esters, causing thermal decomposition. Moreover, the detection of cholesterol and related compounds is not very sensitive in HPLC with ultraviolet detection, since free sterols generally have low absorption coefficients. These problems are avoided with SFC in com-

bination with the highly sensitive FID or with mass spectrometry.

Cholesterol Analysis in Human Serum

The analysis of cholesterol in human serum has been performed with both open tubular and packed column SFC, at temperatures of 65 and 45°C, respectively. With open tubular columns, it is possible to determine quantitatively free, total and individual esterified cholesterol with a simple liquid-liquid extraction without derivatization. The use of FID gives detection limits of 4–6 pg. The quantitative results for the analysis of total cholesterol in reference sera and real samples show good agreement between the SFC, GC (with derivatization), and enzymatic methods.

With columns packed with inert octadecylsilica, there is no need to add any modifier to the carbon dioxide, allowing the simultaneous use of ultraviolet and FID. In addition, the use of carbon dioxide as the supercritical fluid allows ultraviolet detection at wavelengths as low as 190 nm, which are usually below the practical limit with HPLC because of the general absorption of most solvents at this

Figure 2 Chromatograms of cholesterol and cholesteryl esters from human serum reference material with ultraviolet (UV) (wavelength 190 nm) and flame ionization detection (FID). Peak identification: (1) cholesterol, (2) cholesteryl laurate (internal standard), (3) cholesteryl myristate, (4) cholesteryl palmitoleate, (5) cholesteryl linolenate, (6) cholesteryl palmitate + cholesteryl linoleate + cholesteryl arachidonate, (7) cholesteryl oleate, (8) cholesteryl stearate. Chromatographic conditions: reversed-phase HPLC column (250 mm × 4.6 mm i.d.; particle size, 5 μm), column temperature 45°C, CO₂ pressure 200 atm, CO₂ flow rate 750 mL min⁻¹ at room temperature under 760 mmHg. (Reproduced from Nomura *et al.* (1993) *Analytical Chemistry* 65: 1994–1997, with kind permission from the authors and the publisher. Copyright 1993 American Chemical Society.)

wavelength. Use of lower wavelengths in ultraviolet detection results in a greater sensitivity than higher wavelengths for all cholesterol and cholesteryl esters. Both ultraviolet and FID showed good agreement in a study of cholesterol and their esters, with a detection limit of 20 ng for cholesterol and cholesteryl palmitate, though better reproducibility was obtained with UV detection (Figure 2).

Supercritical fluid chromatography can be a useful tool in studies on cholesterol and cholesteryl ester metabolism in serum and biological fluids in general, though some improvements in the selectivity are still needed to properly resolve some difficult pairs of sterol esters.

Cholesterol Analysis in Edible Oils

There are numerous applications of SFC with capillary columns for the determination of components of oils of marine animals especially from Møllerup's group at the Technical University of Denmark (see Table 2). In these samples, numerous lipids have been analysed including cholesterol and its esters, together with vitamin E, squalene, and di- and triglycerides. Open tubular column SFC is therefore very convenient for these complex samples owing to its high resolution and relatively low analysis temperature (150–170°C versus 250–300°C for GC). For example, the analysis of cholesterol and cholesteryl esters in seafood, shark liver, seal and other fish oils has been accomplished with open tubular column SFC both with direct injection of the diluted oil and with previous saponification and fractionation by thin-layer chromatography (see Table 2). The latter purification avoids the overloading of the open tubular columns (100 µm internal diameter) by the squalene that is present in high concentrations in these samples. Saponification followed by fractionation is, however, time consuming and the recovery of minor components can be difficult. With direct injection in SFC, simultaneous determination of cholesterol, triglycerides and other lipids has been achieved, with enhanced separation power compared with HPLC, while gas chromatography always requires sample pretreatment of these oils to ensure chemical stability at high temperatures.

In other solid and more heterogeneous foods, sample preparation is the most time-consuming step in the routine determination of, for instance, cholesterol levels in daily diet and remains the largest source of error in the quantitative analysis of sterols.

Future Trends

Current developments in new types of columns, equipment and detectors for SFC show that this technique is still developing and expanding and will

achieve greater use in the future, particularly with the advent of new chromatographs for packed capillary columns and with automation of modifier addition, which will be very valuable in the determination of more polar sterols and their oxides in samples where high resolution and mild conditions are imperative.

Another important development is the more frequent use of solvents under subcritical conditions which, in practice, is eliminating the rather artificial boundary between SFC and liquid chromatography.

One of the main advantages of using packed capillary columns over conventional packed columns is the improved performance when this separation is coupled to mass spectrometry, thus providing structural determination of the sterols. This is expected to be especially important in the coming years owing to the development of new commercial equipment for SFC-MS.

Another potential source of improvement is the use of new detectors with higher sensitivity than ultraviolet but compatible with the use of modifiers in packed capillary column SFC. The amperometric detector is a good example.

These anticipated developments in SFC technology will be important in the field of sterol analysis, though an automated SFE-SFC without tedious sample preparation and large solvent consumption would be one of the most valuable future developments for sterol analysis.

Sterols are steroid compounds widely distributed in various biological materials, e.g. variety plant and animal lipids, medications, food and dietary supplements. They are basic metabolites in living organisms and they are also precursors of a variety of bile acids, provitamins and steroid hormones. Therefore the analysis of sterols is important in biochemistry, medicine and pharmacy. There is considerable interest in the study of the relationship of plasma cholesterol concentrations to the risk of developing coronary artery disease. Determination of phytosterols and cholesterol is important for the diagnosis of phytosterolaemia and in dietary treatment of hypercholesterolaemia.

The collective name for sterols has been adopted for all naturally occurring crystalline unsaponifiable steroid alcohols. The basic sterol is 5 α -cholestane, and the structure numbering system for sterols are given in **Figure 1**. In general, these compounds are 3-monohydroxysteroids, having 27, 28 or 29 carbon atoms and nearly all have one or more double bonds. The double bond is most commonly found at position 5, with double bonds at C₇ and C₂₂ also being prevalent. Sterols are classified into five groups: cholesterol and its companions, zoosterols, phytosterols, mycosterols and vitamin D. Examples of sterols from each group are given in **Table 1**.

Figure 1 5 α -Cholestane skeleton and numbering system for sterols.

There are four principal methodologies used in sterol chromatography: gravity flow column liquid chromatography (GCC), high performance liquid chromatography (HPLC), gas chromatography (GC) and thin-layer chromatography (TLC). For its selectivity, sensitivity and efficiency, TLC is one of the most frequently employed procedures for the separation of sterols, both for their characterization and for their quantitative analysis.

Preparation of Sample

Since sterols are present in different materials, sample preparation is a very important part of their analysis.

The first step is an extraction procedure which is performed either directly on the previously deproteinized sample or after cleavage of any conjugates present. Diethyl ether, dichloromethane, ethyl acetate, chloroform and other medium polarity organic solvents can be used for extraction.

The next step is purification of the extract or, more exactly, separation of sterols from other lipids, usually by TLC on a silica gel G plate using an *n*-heptane–diethyl ether–acetic acid (85 : 15 : 1) mixture as the mobile phase. Under these conditions the cholesterol and phytosterols are concentrated in one band. Separation and quantitative analysis of individual sterols are performed after elution from the plate by GC, TLC or some other technique.

Some sterols (e.g. vitamin D) are sensitive to atmospheric oxygen, traces of acids and bases, light and heat. Therefore, all steps should be carried out in a cool place, protected from exposure to direct light, and only highly purified solvents should be used.

Stationary Phases and Solvent Systems

Generally, the chromatographic separation of individual sterols is difficult due to the large number of epimers and unsaturated isomers. Various forms of silica gel are most frequently used in the TLC of

Table 1 Examples of sterols

Number of carbon atoms	Trivial name	Systematic name	Group of sterols ^a

sterols; separation can be classified, according to the type of stationary phase, into four main groups: silica gel, silver nitrate silica gel, reversed-phase and bromine-system TLC.

Silica Gel TLC

The separation of individual sterols by adsorption chromatography on silica gel pre-coated plates is relatively easy when there are differences in the type, number, position or configuration of polar groups, but it is difficult in the absence of such differences.

The chromatographic properties of sterols on silica gel G plates using two solvent systems, benzene–diethyl ether (9 : 1) and benzene–diethyl ether (85 : 15) have been studied. The resulting R_F values are listed in Table 2. However, the separation of sterols with these systems is incomplete.

Table 2 Relative retentions of some sterols on silica gel G

Sterol	R_F value	
	System I	System II
Cholesterol	0.20	0.47
7-Dehydrocholesterol	0.19	
Desmosterol	0.20	0.46
Brassicasterol	0.20	
Ergosterol	0.19	0.43
Vitamin D ₂	0.19	
β -Sitosterol	0.20	
Stigmasterol	0.20	
Lanosterol	0.31	0.62

Stationary phase: silica gel G; mobile phase: (I) benzene–diethyl ether (9 : 1); (II) benzene–diethyl ether (85 : 15); visualization: sulfuric acid.

Date from Xu *et al.* (1988).

The separation of cholesterol and cholesterol esters from other lipid fractions on silica gel pre-coated plates using the following solvent systems: first, chloroform–methanol–water (65 : 25 : 4), second, *n*-hexane–acetone (100 : 1) and third, *n*-hexane–acetone (100 : 3) has also been reported. The plates are developed with the first solvent system to 8 cm from the origin. After drying, the plates are developed to 18 cm above the origin with either of the other solvent systems. Cholesterol and four cholesterol ester subfractions are separated from other lipid fractions.

Silica gel GF plates have been used to separate cholesterol, cholesteryl propionate and low molecular weight cholesteryl esters by one-stage one-dimensional TLC. This work employed four solvent systems, the best separation among cholesteryl formate, cholesteryl acetate and cholesteryl propionate was achieved using chloroform–diethyl ether–acetic acid–1-propionic acid (92 : 1.5 : 1 : 5 : 0.5).

The solvent systems used for the separation of eight 3 β -sterols of considerable biological interest, which differ only in ring B and/or in the side chain, on silica gel G pre-coated plates has also been investigated. The separation was performed using first, cyclohexane–ethyl acetate–water (600 : 400 : 1); second, cyclohexane–heptane (1 : 1), third, cyclohexane–ethyl acetate–water (1560 : 440 : 1), and fourth, isooctane–carbon tetrachloride (19 : 1). Differences in resolving power between polar and nonpolar systems were observed. Resolution of the pairs with saturated and unsaturated side chain β -sitosterol–stigmasterol and cholesterol–desmosterol was finally effected by a mixture of saturated hydrocarbons.

Separation of vitamin D from its close structural analogues, including provitamin D, irradiation

products of provitamin D and decomposition products, has been carried out on nonimpregnated layers of silica gel G with the solvent system cyclohexane–dichloroethane–diethyl ether (5 : 3 : 2). TLC has also been used for pre-purification of saponified samples before GC analysis as well as for their *in situ* quantitative analysis. Determination of the maximum permissible limit of concentration of ergosterol in ergocalciferol using silica gel G as the stationary phase with a cyclohexane–peroxide-free ether (1 : 1) mixture containing 0.1 g L⁻¹ butylhydroxytoluene is an official method in the European Pharmacopoeia 1997.

In general, monosaturated sterols like cholesterol, provitamin D (e.g. ergosterol) and vitamins D are separable, but closely related sterols like cholesterol, stigmasterol and β -sitosterol are not resolved on silica gel.

Silver Nitrate TLC (Argentation Chromatography)

Several methods have been published for separation of structurally related sterols. A procedure utilizing π -complex formation between Ag(I) ions and the double bonds occurring in various locations in the sterol molecules has been frequently applied. Argentation TLC is a method for separating compounds based on differences in number and position of double bonds in the molecule. In this case, silica gel is suspended in an aqueous solution of silver nitrate before spreading on the plate. Silver nitrate can also be sprayed on to a pre-prepared layer.

Argentation TLC of sterols has been thoroughly investigated. The R_s values (relative retention relating to cholesterol) of selected sterols and sterol acetates separated on silica gel G–silver nitrate pre-coated plates using the solvent systems chloroform–diethyl ether–acetic acid (97 : 2.3 : 0.5) and chloroform–light petroleum (b.p. 60–80°C)–acetic acid (25 : 75 : 0.5) are listed in Table 3.

Sterols that differ in the number and position of double bonds are clearly separated by means of silver nitrate TLC, but separation of cholesterol from the phytosterols was not achieved.

Reversed-phase TLC

One of the pioneer works on reversed-phase TLC (RP-TLC) used silica gel impregnated with paraffin oil as the stationary phase and methyl ethyl ketone as the mobile phase for the separation of lipids, including cholesterol esters. Kieselguhr G has been used following impregnation with undecane as the stationary phase with the solvent systems acetic acid–water (90 : 10) and acetic acid–water (92 : 8) for the separation of sterols and sterol acetates, respectively. R_s values of some sterols and sterol acetates obtained by RP-TLC are given in Table 4.

Table 3 Separation of sterols and sterol acetates on silica gel G–silver nitrate layers

Sterol	R_s value	
	System I (sterols)	System II (sterol acetates)
Cholesterol	\equiv 1.00	\equiv 1.00
7-Dehydrocholesterol	0.44	0.43 ^a
Dihydrocholesterol	1.14	1.25
Brassicasterol	0.98	0.68
Vitamin D ₂	0.64	
Dihydro- β -sitosterol	1.14	1.30
β -Sitosterol	1.00	1.00
Stigmasterol	0.98	0.87
Lanosterol	1.70	0.78

^aAfter two developments.

Stationary phase: silica gel G–silver nitrate. Mobile phase: (I) chloroform–diethyl ether–acetic acid (97 : 2.3 : 0.5); (II) chloroform–light petroleum (b.p. 60–80°C)–acetic acid (25 : 75 : 0.5). Visualization: dibromofluorescein.

Data from Copius-Peereboom and Beekes (1965).

The critical pair cholesterol–brassicasterol was not separated in these RP systems and RP-TLC separation according to the degree of unsaturation using the so-called bromine system was suggested (see below).

A good separation of the pairs vitamin D₂/D₃ and pre-vitamin D₂/D₃ on silica gel and Kieselguhr G impregnated with silicone oil eluted with acetone–water mixture has been achieved.

The Bromine System TLC

The separation of unsaturated sterols from their saturated analogues can be substantially improved by

Table 4 R_s values of some sterols and sterol acetates obtained in RP-TLC

Sterol	R_s value	
	System I (sterols)	System II (sterol acetates)
Cholesterol	\equiv 1.00	\equiv 1.00
7-Dehydrocholesterol	1.12	1.26
Dihydrocholesterol	0.90	0.89
Brassicasterol	1.00	1.00
β -Sitosterol	0.86	0.83
Stigmasterol	0.93	0.91
Lanosterol	0.84	0.97

Stationary phase: Kieselguhr G impregnated with undecane; mobile phase: (I) acetic acid–water (90 : 10); (II) acetic acid–water (92 : 8), visualization: phosphomolybdic acid.

Data from Copius-Peereboom JW and Beekes HW (1962). The analysis of mixtures of animal and vegetable fats. III. Separation of some sterols and sterol acetates by thin-layer chromatography. *Journal of Chromatography* 9: 316.

Table 5 R_s values of some sterols acetates in the bromine system TLC

<i>Sterol acetates</i>	R_s
Cholesterol	$\equiv 1.00$
7-Dehydrocholesterol	Front
Dihydrocholesterol	0.85
Brassicasterol	1.13
β -Sitosterol	0.82
Stigmasterol	1.06
Lanosterol	Front

Stationary phase: Kieselguhr G impregnated with undecane; mobile phase: acetic acid–acetonitrile (1 : 3) + 0.5% of bromine, visualization: antimony trichloride.

Data from Copius-Peereboom and Beekes (1965).

bromination. After spotting the sterol sample at the starting zone, some drops of bromine are spotted on the same place. The plate is then developed with a benzene–ethyl acetate mixture (2 : 1), by means of which the spots of cholesterol and dihydrocholesterol are separated. Thus, sterol acetates have been separated

on Kieselguhr G impregnated with undecane using solvent system acetic acid–acetonitrile (1 : 3) + 0.5% bromine. R_s values of some sterol acetates are given in Table 5.

Bromination of the double bonds before or during chromatography completely changes the mobilities of the unsaturated compounds, promoting their separation from the saturated derivatives. In this way the critical pair cholesterol–brassicasterol can be clearly separated.

Detection and Quantitation

Detection

Sterols that have UV absorbance can be detected at 254 nm (providing that TLC separation is performed on a layer with a fluorescent indicator). Since a number of sterols do not have UV absorbance suitable for detection, most applications still involve visualization based on chemical reactions. Visualization procedures used to detect and characterize sterols are well

Table 6 Detection procedures based on chemical reactions used in TLC analysis of sterols

<i>Detection reagent</i>	<i>Visualization procedure</i>	<i>Sterols</i>
<i>Acids</i>		
Perchloric acid (70%)	Spray	Vitamin D ₂
Phosphomolybdic acid (15% ethanolic solution)	Spray, heat at 110°C for 10 min	Various sterols
Sulfuric acid (conc. or 50%)	Spray, heat at 110°C for 15 min, observe in day and UV light before and after heating	C ₂₇ sterols, cholestane and lanostane series, ergosterol
<i>Metal salts</i>		
Antimony pentachloride (30% in chloroform)	Spray, heat at 120°C for 5 min	Various sterols
Antimony trichloride (50% in conc. acetic acid)	Spray, heat at 100°C for 10 min	Brominated sterols
Cadmium chloride (50% in 50% ethanol)	Spray, heat at 90°C for 15 min, observe in UV light	Brominated sterols, cholesteryl esters
Copper sulfate		Saturated species
Cupric acetate (3% in 8% phosphoric acid)	Spray, heat at 150°C for 30 min	Unsaturated species
<i>Aldehydes</i>		
<i>p</i> -Anisaldehyde (1% in acetic acid–sulfuric acid (98 : 2) mixture)	Spray, heat at 90°C for 10 min	Sterol and sterol acetates
Salicylaldehyde	Spray with pure salicylaldehyde, heat at 80°C for 5 min, spray with 0.5 mol L ⁻¹ sulfuric acid, heat again at 90°C for 10 min	Sterol and sterol acetates
Vanillin (0.5% in sulfuric acid–ethanol (4 : 1) mixture)	Spray, heat at 100°C for 5 min	Cholestanols and cholestanones
<i>Ketone reagents</i>		
2,4-Dinitrophenylhydrazine (5% in methanol)	Spray and spray again with conc. sulfuric acid	Ketonic sterols

established. Detection reagents can be classified into four groups: acids, metal salts, aldehydes and ketone reagents. The most frequently used detection procedures are listed in Table 6.

TLC coupled with flame ionization detection (TLC-FID) has been used to detect sterols. The separation is performed on specially prepared thin quartz rods coated with adsorbent sintered on to the surface of thin rods. The adsorbent is usually silica gel and the solvent system is basically the same as in classical TLC.

TLC-FID is a useful technique for the separation of cholesterol and its esters from other lipid classes. Separation of individual sterols, especially phytosterols (e.g. β -sitosterol, campesterol, brassicasterol, stigmasterol, etc.) using TLC-FID is not possible. On the other hand, groups of sterols differing in the number of methyl groups in position 4 (i.e. 4-demethylsterols, 4-methylsterols and 4,4-dimethylsterols) can easily be separated by TLC-FID.

The TLC separation of sterols is often used for preparative purposes. After elution from the plate, the sterols can be analysed by some other technique (spectrophotometry, fluorimetry, GC, GC-MS, HPLC), which is why it is sometimes necessary to visualize them using nondestructive reagents such as iodine vapour, water spray or fluorescent reagents (e.g. fluorescein, Rhodamine B). Fluorescent reagents can be incorporated in the slurry, during the preparation of the layer. An example of a nondestructive detection using radiolabelled [4- 14 C] cholesterol and cholesteryl [14 C]oleate added as internal standards has also been reported where desmosterol in monkey spermatozoa was separated on silica gel G. The free sterol band containing both cholesterol and desmosterol was detected, extracted from the plate and after, derivatization, analysed by GC.

Quantitative *in situ* Analysis

Due to progress in plate technology and instrumentation, modern TLC has become a comparable method to other chromatographic techniques in terms of accuracy, precision, reliability and repeatability. In modern TLC, the main steps are automated, including the sample application on the plate – the step considered the most critical for quantitative evaluation. Several examples of direct quantitation of sterols on TLC plate are discussed below.

Cholesterol ester mapping of human serum by high performance TLC (HPTLC) has been performed. Quantitative analysis was carried out at 546 nm after postchromatographic derivatization with phosphomolybdic acid. The densitogram of a standard mixture containing cholesterol esters is given in Figure 2.

Figure 2 Densitogram of a standard mixture containing 33 ng of each cholesterol ester. 1, Cholesterol palmitate; 2, cholesterol oleate; 3, cholesterol linolate; 4, cholesterol linoleate. Separation was performed on HPTLC Kieselgel 60 F₂₅₄ (Merck) in carbon tetrachloride solvent system. (Reproduced with permission from Kovács *et al.*, 1989. Copyright 1989 American Association for the Advancement of Science.)

HPTLC silica gel plates and a dual solvent system, consisting of a run with isopropyl ether–acetic acid (96 : 4) followed by a run in the same direction with petroleum ether (b.p. 60–70°C)–diethyl ether–acetic acid (90 : 10 : 1) has been to determine cholesterol in egg yolk as well as in butter and cream samples. Cholesterol was detected with cupric acetate reagent, lipid zones were quantified by densitometry.

Quantitative measurement of free cholesterol in serum on a silica gel/sodium carboxymethylcellulose plate has also been reported. The solvent system was petroleum ether–ethyl acetate–glacial acetic acid (80 : 20 : 1). Spraying with vanillin was used for visualization. The colour of the cholesterol spot was stable for *c.* 20 min. *In situ* measurement was done by densitometry at 525 nm with a detection limit of 40 ng per spot. The peak area was linearly related to the amount of cholesterol over the range 80–700 ng per spot.

Cholesterol, cholesteryl esters and other neutral lipids have been analysed in plasma by TLC-FID. Separation was performed on Chromarods S with hexane–diethyl ether–formic acid (52 : 8 : 0.1).

Quantitative *in situ* analysis of vitamin D in cod liver oil has been demonstrated by measuring absorbance at 268 nm on silica gel layers after dual development (first with *n*-hexane, then with cyclohexane–diethyl ether (1 : 1) mixture). Vitamin D was also determined in foods and in human milk by *in situ* reflectance measurement.

TLC and Characterization of Sterols

The chromatographic behaviour of each compound depends on the stereochemistry and location of polar

Figure 3 Relationship between R_S values and the carbon numbers for sterol acetates in RP-TLC; coefficient of linear correlation, $R = 0.9793$. Stationary phase: Kieselguhr G impregnated with undecane; mobile phase: acetic acid–acetonitrile (1 : 3). Nc = number of carbon atoms – number of double bonds. (Data from Copius-Peerboom and Beekes, 1965.)

substituents, the solubility, partition coefficients and equilibrium constants of the compound in the solvent system, the size and shape of the molecule and the degree of hydration. The quantitative structure–chromatographic retention relationship study between sterols, TLC mobilities and their structures has been investigated by several authors.

A separation of steroids according to the degree of unsaturation has been investigated. In structural analysis, argentation TLC and the bromine system can give information about the number and position of double bonds in a molecule. A linear relationship between the R_S value and carbon numbers (Nc = number of carbon atoms – number of double bonds) in the system undecane/acetic acid–acetonitrile (1 : 3) for saturated and Δ^5 -unsaturated sterols has been found. This linear relationship is shown in Figure 3.

Adsorption TLC is not only a method of sample purification, but the R_F value also provides a clue to the compound's structure. The structural feature that mostly contributes to the chromatographic behaviour of sterols in adsorption TLC is the presence of a free 3β -OH group. Converting the 3β -OH to an acetoxy, methoxy, keto, or 3α -OH results in a steroid with a less polar R_F value relative to the R_F value obtained for cholesterol.

Separation of individual cholesterol ester subfractions according to the sum of the carbon atoms and numbers of double bonds in their fatty acid moieties has been performed.

The elution order of vitamin D photoisomers can be correlated with the increasing planarity of the molecules. R_F values of vitamin D photoisomers on silica gel with solvent system cyclohexane–dichloroethane–diethyl ether (5 : 3 : 2) were 0.18 (pro-vitamin D_3), 0.23 (tachysterol₃), 0.27 (lumisterol₃) and 0.31 (pre-vitamin D_3).

A visualization procedure can give additional information about sterol structure, since different reagents produce different colours with individual sterols. Some reagents are specific for individual functional group (e.g. 2,4-dinitrophenylhydrazine for keto group).

Future Developments

A general tendency in modern TLC is separation on HPTLC stationary phases, online coupling with other separation techniques (e.g. HPLC-TLC), as well as online coupling with spectroscopic methods. *In situ* recording of UV-visible spectra is most commonly used. However, the recording of Fourier transform infrared, Raman or mass spectra is more informative. Although these combinations have frequently been reported in the literature, there is still no example of their application in the field of sterol analysis. Due to the great variety of chemically closely related sterols, online combination of TLC and spectroscopic methods can be considered a powerful tool for their isolation and *in situ* characterization.

STRONTIUM FROM NUCLEAR WASTES: ION EXCHANGE

P. Sylvester, Texas A & M University, College Station, TX, USA

Copyright © 2000 Academic Press

Introduction

The development of new inorganic ion exchange materials for the selective removal of strontium and other radionuclides from nuclear waste has progressed rapidly in recent years. ^{90}Sr is an important component of many nuclear wastes and is a high yield fission product of ^{235}U . It is relatively short-lived with a half-life of 28.8 years and, along with ^{137}Cs , is the source of a large percentage of the initial radioactivity and heat generation of spent nuclear fuel. During the reprocessing of nuclear fuel, irradiated uranium fuel rods are dissolved in nitric acid and uranium and plutonium are separated from the fission products and other actinides by means of the Purex process. Tributylphosphate (TBP) dissolved in an organic phase, such as odourless kerosene, is contacted with the nitric acid solution, and plutonium and uranium nitrates are selectively complexed by the TBP and extracted into the organic

phase. The majority of fission products, including ^{90}Sr , remain in the aqueous acidic phase, which can then be concentrated by means of evaporation and stored prior to permanent disposal. In addition to the acidic high level waste stream, numerous other streams are generated during reprocessing operations as a result of washing, decontamination and scrubbing operations. Details of some specific streams generated by the nuclear industry from which ^{90}Sr needs to be selectively removed from large excesses of inert ions will be given later in this article.

A convenient method of selectively removing contaminant species from higher concentrations of inert ions is by ion exchange. Organic ion exchange resins are used in many industries for the selective removal of ions from aqueous streams. These materials consist of a polymeric backbone (commonly polystyrene) to which has been attached functional groups such as carboxylic or sulfonic acids to produce cation exchangers, or tertiary or quaternary amines to produce anion exchange resins. However, the use of organic resins in the nuclear industry is limited for a number of reasons. These include:

- low resistance to damage by ionizing radiation, thus limiting operational life;
- low thermal stability;
- limited chemical stability;
- low selectivity in comparison to inorganic ion exchange materials;
- incompatibility with grout or cement, making the final disposal of spent resins a problem.

Inorganic ion exchangers offer a number of advantages over conventional organic resins including greater selectivity and both chemical and radiolytic stability. Additionally, they are compatible with current waste encapsulation techniques and are stable enough that they can be used as a final waste form for long-term storage. The major drawback to the use of inorganic ion exchangers is that they are typically synthesized as fine powders, which are unsuitable for use in column operations. However, there are now a number of techniques available to allow these powders to be produced as pellets or particles suitable for column operations, while still retaining fast ion exchange kinetics and the ion selectivity of the original material. A number of reviews of available materials and their ion exchange selectivities have been written, and as new materials and methods of manufacture are being developed, the use of inorganic materials both in the nuclear industry and elsewhere will undoubtedly expand. Some of the major classes of materials that are currently being used (or are under evaluation) for the selective removal of ^{90}Sr from nuclear wastes are described in the following sections.

Zeolites

Zeolites are hydrated aluminosilicates with open framework structures. These consist of building blocks of $\{\text{SiO}_4\}$ and $\{\text{AlO}_4\}$ tetrahedra which can be interlinked to give a wide range of different materials with regular tunnels and cavities. The presence of trivalent aluminium in the framework results in a net negative charge that is neutralized by the absorption of cations. Specific zeolites exhibit high selectivities for strontium and caesium over other alkali and alkaline earth cations. This has led to their use in the treatment of some nuclear waste streams. Details of zeolite synthesis, structures, applications and information on their ion exchange properties can be found in the literature and will not be detailed in this article.

Clinoptilolite is a common natural zeolite with the ideal formula $\text{Na}_6\text{Al}_6\text{Si}_{30}\text{O}_{72} \cdot 24\text{H}_2\text{O}$, though due to interactions with natural groundwaters, some of the Na^+ ions will have been replaced by K^+ , Mg^{2+} and Ca^{2+} ions. It is currently used on a large scale both in the UK and the USA for the treatment of nuclear

waste solutions such as cooling pond water. This is one of the largest waste streams in terms of the volume of liquid, and consists of water used to cool and shield irradiated uranium fuel rods prior to their disposal or reprocessing. For example, spent pressurized water reactor (PWR) fuel is generally stored under water for up to 5 years to allow short-lived radioisotopes, such as ^{131}I ($T_{1/2} = 8.06$ days) and ^{106}Ru ($T_{1/2} = 367$ days), to decay away, and thus make the fuel rods easier to handle. Storage is often accompanied by the release of tiny amounts of radioactivity, primarily ^{137}Cs and ^{90}Sr , from the fuel rods into the cooling water thus necessitating removal of the radioactivity before the water can be discharged to the environment. Modern fuel is typically clad in zircalloy or stainless steel and the release of radioisotopes is minimal. However, older fuel types such as the UK's Magnox fuel and fuel stored at the Hanford site in Washington State, USA, do release significant radioactivity.

Fuel storage pond waters are relatively pure and contain minimal dissolved cations that can compete with the ^{90}Sr and ^{137}Cs for the available ion exchange sites. Compositions of a fuel pond simulant from the Hanford site and the composition of an average pond water from the British Nuclear Fuels plc. (BNFL) Sellafield, UK site are given below in **Table 1**.

At the Sellafield plant, BNFL employs two 9.6 m^3 beds of clinoptilolite in the site ion exchange effluent plant (SIXEP) to decontaminate the pond water used for storage of Magnox fuel before controlled discharge to the sea. This clinoptilolite originates from the Mud Hills deposit in the Mojave Desert, California, and has been crushed and sieved to give a particle size of 0.4–0.8 mm in diameter. A schematic of the SIXEP plant is given in **Figure 1**.

Table 1 Composition of two fuel cooling ponds

Component	Hanford N-basin (ppm)	Sellafield (ppm)
Al	0.78	0.3
B	28.4	nd
Ba	3.1	0
Ca	33.4	1.7
Cs	6.47×10^{-5}	3217 Bq mL^{-1a}
K	2.5	3.6
Mg	0.70	0.3
Na	37.2	48.5
Sr	0.39	287 Bq mL^{-1a}
pH	8.2	11.4

^a The activities of ^{90}Sr and ^{137}Cs correspond to pondwater concentrations of 5.38×10^{-5} ppm and 8.69×10^{-4} ppm, respectively. There is unlikely to be significant nonactive caesium present; however, the amount of nonactive strontium is likely to be significantly greater than the ^{90}Sr concentration. nd, not determined.

Figure 1 Schematic of BNFL's site ion exchange effluent plant (SIXEP). (Reproduced with the permission of BNFL.)

The feed is pumped through a sand filter to remove any particulates and is then treated with carbon dioxide to decrease the pH to approximately 7. The feed passes through two beds of clinoptilolite in series before being sampled and discharged to the Irish Sea. On average, approximately 3000 m³ of effluent per day pass through the plant, which corresponds to a contact time of only 4.6 minutes per ion exchange bed. The clinoptilolite is very effective and typically removes 98.7% of the strontium and over 99.7% of the caesium from the stream prior to its discharge, and each bed lasts for approximately 6 months online.

Another area in which zeolites can be used for the removal of radioactive strontium is in groundwater remediation. Groundwaters have relatively low ionic strengths similar to pond waters, but differ in that the predominant inactive ions in solution are magnesium and calcium rather than sodium. There is also natural, nonradioactive strontium present, typically in the order of a few tenths of a part per million, which will also be removed along with the radioactive ⁹⁰Sr. Since Mg²⁺ and Ca²⁺ compete strongly with Sr²⁺ for the available ion exchange sites on the zeolites, the observed distribution coefficients (K_{ds}) for Sr tend to be considerably lower than in pond waters, and the higher concentration of strontium results in a shorter ion exchange bed life. However, the low cost of natural zeolites (less than US \$0.5 per lb for clinoptilolite) means that they are economically viable.

Sodium Nonatitanate

Sodium nonatitanate (NaTi), Na₄Ti₉O₂₀ · xH₂O, displays a very high selectivity for strontium in basic

media. The synthetic procedure is relatively simple and has been scaled up to allow the titanate to be produced on an industrial scale. A soluble source of titanium, such as titanium isopropoxide, is added to a 50% sodium hydroxide solution, resulting in the immediate formation of a white precipitate. The mixture is then heated in a hydrothermal bomb for approximately 21 h at a temperature of 200°C. The product is filtered, washed to remove excess NaOH, and dried to produce a white powder. The final material has a low crystallinity and consequently it has not been possible to determine the crystal structure. However, the titanate is believed to consist of layers of TiO₆ octahedra separated by exchangeable sodium ions and water molecules. At room temperature, the interlayer space is approximately 10 Å, but the distance can vary considerably depending upon the drying temperature, and hence the number of water molecules in the interlayer space. This material is now available from Allied Signal Inc. (Des Plaines, Illinois, USA) and similar products can also be obtained from Selion Inc. (Merden, Connecticut, USA) and Boulder Scientific Company (Mead, Colorado, USA).

Sodium nonatitanate exhibits a very high selectivity for strontium over alkali and other alkaline earth metals in basic media. In acidic media, the material has a high affinity for protons, so strontium selectivity is negligible. Consequently, this allows the nonatitanate to be stripped of absorbed strontium using dilute acid and reused. Sodium nonatitanate readily hydrolyses in water, exchanging protons for sodium ions; this results in a considerable increase in the solution pH. Consequently its use for treating groundwaters contaminated with ⁹⁰Sr is limited. However, its stability in highly

alkaline conditions makes it ideally suited for the treatment of alkaline nuclear wastes. This aspect will be discussed later.

Titanosilicates

Two separate classes of titanosilicate ion exchange materials have been developed for the selective extraction of strontium from nuclear wastes. Both classes are composed of a titanosilicate framework, but the crystal structures and the Ti:Si ratios are different and hence so are the ion exchange properties.

The first class of materials is exemplified by sodium titanosilicate (NaTS), with the ideal formula $\text{Na}_2\text{Ti}_2\text{O}_3\text{SiO}_4 \cdot 2\text{H}_2\text{O}$. This can be synthesized in a crystalline form which has allowed its structure to be determined using X-ray powder methods. The titanosilicate was found to have a tetragonal unit cell with $a = b = 7.8082(2) \text{ \AA}$ and $c = 11.9735(4) \text{ \AA}$. Edge-sharing TiO_6 clusters reside in all eight corners of the unit cell and silicate tetrahedra are located midway between the clusters and link them together. This arrangement produces tunnels parallel to the c -axis where the exchangeable sodium ions and the water molecules reside. The remaining sodium ions are located in the framework, bonded by silicate oxygens and are thus not exchangeable. Due to steric repulsions and space limitations, some of the sodium ions in the tunnels are replaced by protons, leading to an actual formula of $\text{Na}_{1.64}\text{H}_{0.36}\text{Ti}_2\text{O}_3\text{SiO}_4 \cdot 1.84\text{H}_2\text{O}$. This exchanger is synthesized by hydrothermally heating a titanium silicate gel of appropriate stoichiometry in $6 \text{ mol L}^{-1} \text{ NaOH}$ at 170°C for 2 days.

This material has been shown to have a high selectivity for Cs^+ ions in both acid and alkaline pH and a high selectivity for strontium in alkaline media. Caesium ions exchanged onto the titanosilicate are strongly held in the tunnels, as shown in Figure 2, and are not readily leached off, thus the material is not regenerable. Strontium is readily removed by washing with dilute acid. A related material is currently marketed by UOP as a crystalline silicotitanate (CST) under the tradename IE-910 for the powder, and IE-911 for an engineered form suitable for use in column operations. The CST has shown excellent selectivity for ppm levels of caesium ions in the presence of $7 \text{ mol L}^{-1} \text{ Na}^+$ ions and is currently being considered for use removing ^{137}Cs and ^{90}Sr from alkaline nuclear wastes in the USA.

The second class of titanosilicate materials has the crystal structure of the natural mineral pharmacosiderite. Pharmacosiderite has the ideal formula $\text{KFe}_4(\text{AsO}_4)_3(\text{OH})_4$ and crystallizes in the cubic

Figure 2 The structure of the caesium-exchanged titanosilicate showing Cs^+ ion in the centre of the tunnel.

system. Titanosilicates with the general formula $\text{M}_3\text{H}(\text{AO})_4(\text{BO}_4)_3 \cdot 4\text{--}6\text{H}_2\text{O}$ ($\text{M} = \text{H, K, Na, etc.}$; $\text{A} = \text{Ti, Ge}$; $\text{B} = \text{Si, Ge}$) have been prepared using hydrothermal techniques. A homogeneous gel of appropriate stoichiometry was hydrothermally treated in an excess of either KOH or CsOH at 200°C for 1–3 days. Sodium and proton forms were then prepared by exhaustively ion exchanging the material with either HCl or NaCl . The best studied of these materials is the potassium pharmacosiderite, $\text{K}_3\text{H}(\text{TiO})_4(\text{SiO}_4)_3 \cdot 4\text{H}_2\text{O}$ (KTS-Ph), in which $a = b = c = 7.7644(3) \text{ \AA}$. Each unit cell consists of

Figure 3 The structure of potassium pharmacosiderite $\text{HK}_3(\text{TiO})_4(\text{SiO}_4)_3 \cdot 4\text{H}_2\text{O}$ with the K^+ ion located in the centre of the tunnels. $a = b = c = 7.7644(3) \text{ \AA}$.

clusters of four titania octahedra linked to each other by silicate groups, as shown in Figure 3. This produces a series of intersecting tunnels parallel to the *a*, *b* and *c* axes with the exchangeable ions residing close to the face-centres of the unit cell.

It has proved possible to substitute Ge for both Si and Ti in the pharmacosiderite framework, thus allowing the size of the tunnels to be carefully tailored. These materials have shown selectivity towards both Cs^+ and Sr^{2+} but are not as effective as the sodium titanosilicate, NaTS, described previously. However, the caesium ion can be eluted from the exchanger, so unlike NaTS, the pharmacosiderites are regenerable making them more cost-effective.

Removal of Strontium from High Ionic Strength Wastes

In the USA, there are over 100 million gallons of radioactive mixed waste stored in 332 tanks distributed over a number of Department of Energy (DOE) sites. Much of this tank waste is highly alkaline and is typically over 7 mol L^{-1} in Na^+ . The majority of this waste is found at the Hanford site in Washington State, where there is approximately 65 million gallons of high-level waste stored in 177 tanks. All of the Hanford tanks are highly alkaline and were generated as by-products of the production of ^{239}Pu for nuclear weapons manufacture. Initially, the waste was in a nitric acid matrix, but to minimize corrosion of the steel tanks, sodium hydroxide was added to neutralize the wastes and to precipitate much of the radioactivity. The composition of each tank is different, but in general, the wastes consist of three distinct phases. At the bottom of the tank is a metal hydroxide sludge, at the top is a salt cake, predominantly made up of nitrate salts, and between these layers is an alkaline supernate. ^{90}Sr is found in all three layers, but tends to predominate in the sludge layer. However, in cases where there are significant amounts of complexing agents, considerably greater ^{90}Sr activity is found in the supernate. The composition of two supernate simulants developed at Pacific Northwest National Laboratory (PNNL) to mimic the tank wastes are given in Table 2.

Both waste simulants represent dilution of actual tank wastes, which is envisaged to be necessary to allow ease of handling without excessive precipitation of salts occurring. NCAW represents tank 241-AZ-102, and 101-SY represents tank 241-SY-101, both diluted to approximately 5 mol L^{-1} in Na^+ . This latter tank contains significant amounts of complexants such as ethylenediaminetetraacetic acid (EDTA) and citric acid. Zeolites are unsuitable for the treatment of these tank wastes because they lack sufficient selectiv-

ity for strontium in the presence of high sodium concentrations, and they are also unstable in highly alkaline conditions. However, the titanate and the titanosilicates are synthesized in strongly alkaline media and thus exhibit a high stability in these tank wastes. In addition, all of the exchangers exhibit good radiation stability, thermal stability and excellent resistance to extreme chemical environments.

The sodium nonatitanate and the titanosilicate ion exchange materials were evaluated in preliminary batch experiments using ^{89}Sr as a surrogate for ^{90}Sr . Here, 0.05 g of exchanger was contacted with 10 mL of waste simulant spiked with ^{89}Sr , giving a volume to mass ratio of 200 : 1, for 18 h using a rotary shaker. The mixtures were then filtered through a $0.2 \mu\text{m}$ filter and the activity of the aqueous phase determined using liquid scintillation counting. K_d values for strontium were then calculated according to eqn [1] below:

$$K_d = (A_i - A_f)/A_f \times v/m \quad [1]$$

where A_i is the initial activity of solution (counts per minute mL^{-1}); A_f is the final activity of solution (counts per minute mL^{-1}); v is the volume of solution (mL); and m is the mass of exchanger (g).

Table 2 The composition of two Hanford tank waste simulants

Species	NCAW (mol L^{-1})	101-SY (mol L^{-1})
Al	0.43	0.42
Ca	0	4.20×10^{-3}
Cs	5.00×10^{-4}	4.19×10^{-5}
Fe	0	1.96×10^{-4}
K	0.12	0.034
Mo	0	4.20×10^{-4}
Na	4.99	5.1
Ni	0	2.50×10^{-4}
Rb	5.00×10^{-5}	4.20×10^{-6}
Sr	2.70×10^{-7}	4.10×10^{-6}
Zn	0	5.00×10^{-4}
Carbonate	0.23	0.038
Fluoride	0.09	0.092
Hydroxide	3.4	3.78
Hydroxide (free)	1.68	2.11
Nitrate	1.67	1.29
Nitrite	0.43	1.09
Sulfate	0.15	4.75×10^{-3}
Phosphate	0.025	0.02
Citric acid	0	5.00×10^{-3}
Na_4EDTA	0	5.00×10^{-3}
HEDTA	0	3.75×10^{-3}
Iminodiacetic acid	0	0.031
Na_3 nitrilotriacetate	0	2.50×10^{-4}
Sodium gluconate	0	0.013
pH	14.5	14.4

HEDTA, *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid.

Table 3 The removal of strontium from Hanford tank waste simulants by inorganic ion exchange materials

<i>Ion exchanger</i>	<i>NCAW, K_d (mL g⁻¹)</i>	<i>% Sr removed</i>	<i>101-SY, K_d (mL g⁻¹)</i>	<i>% Sr removed</i>
Clinoptilolite	48	19.35	Not tested	–
NaTi	235 000	99.93	295	61.1
NaTS	270 000	99.93	231	54.7
KTS-Ph	20 200	99.55	31	13.2

The results obtained for the three ion exchangers are displayed in Table 3. For comparative purposes, the strontium K_d for the Mud Hills clinoptilolite was also included, although this number should be viewed with caution because clinoptilolite is not stable in highly alkaline media and will have undergone substantial decomposition.

It can be seen that all of the synthetic ion exchange materials exhibited a very high selectivity for strontium from NCAW with K_d values in the tens or hundreds of thousands. Clinoptilolite performed very poorly, with a K_d of only 48 mL g⁻¹ compared with the best material, the sodium titanosilicate, which had a K_d of 270 000 mL g⁻¹. By contrast, the K_d values from the 101-SY simulant were very low for all of the materials, indicating that the presence of relatively high concentrations of EDTA, citric acid and other complexants has resulted in the strontium being strongly chelated and thus not readily extractable by ion exchange. However, recent studies have indicated that this problem can be overcome by the addition of Ca²⁺ or other ions to the waste in sufficient quantity to saturate all of the EDTA and other complexants present, and thus release the strontium into solution where it can be removed by strontium-selective ion exchangers. Alternatively, the complexants can be destroyed using an appropriate chemical oxidation technique and the strontium removed by ion exchange.

Column Experiments

Column experiments using ⁸⁹Sr-spiked NCAW were performed to further evaluate the efficiency of the sodium nonatitanate, the sodium titanosilicate and the potassium pharmacosiderite at removing Sr under dynamic conditions. This necessitated pelletizing the ion exchange materials using approximately 15% by weight of a hydrous titania binder. Hydrous titania also shows some affinity for strontium in alkaline media, but tests proved that the K_d values were insignificant in comparison to the ion exchange materials.

Approximately 1 mL of material was slurried into a column and NCAW, spiked with ⁸⁹Sr to give a total strontium concentration of 2.7×10^{-7} mol L⁻¹, was then passed through at a flow rate of approximately 20 bed volumes per hour (BV h⁻¹). The ⁸⁹Sr activity

in the solution exiting the column was then analysed using liquid scintillation counting. Percentage breakthrough was calculated according to eqn [2]:

$$\% \text{Breakthrough} = (A_f/A_i) \times 100 \quad [2]$$

where A_f is the ⁸⁹Sr activity exiting the column and A_i is the ⁸⁹Sr activity entering the column.

The breakthrough curves obtained for the materials are given in Figure 4. Also included is the breakthrough curve for the commercially available IE-911 determined under the same operating conditions. The nature and percentage binder present in the IE-911 is unknown, but in simple batch equilibrium experiments Sr K_d values in excess of 25 000 mL g⁻¹ were obtained for ⁸⁹Sr in NCAW. Figure 4 shows that breakthrough of ⁸⁹Sr from the IE-911 bed is almost instantaneous, indicating very poor kinetics of exchange. By contrast, all three of the other exchangers show < 5% ⁸⁹Sr breakthrough for over 1500 bed volumes. Breakthrough was first obtained for the potassium pharmacosiderite and was followed by the sodium titanate and had reached approximately 25% and 17% respectively after 3000 bed volumes had been passed. By contrast, the breakthrough for the titanosilicate was still only around 5% when the experiment was terminated after the passage of 3500 bed volumes. This indicates rapid kinetics for all of the materials except the IE-911 and also an appreciable capacity for

Figure 4 ⁸⁹Sr breakthrough curves for IE-911, NaTi, NaTS and KTS-Ph for NCAW at a flow rate of 20 BV h⁻¹.

strontium. Thus, all of the materials, particularly the sodium titanasilicate, have good potential for the decontamination of high-salt, alkaline nuclear wastes.

Conclusions

Inorganic ion exchangers have a wide number of applications within the nuclear industry and are preferred over conventional organic resins. Zeolites are ideal for the treatment of dilute wastes, provided that the pH is not too extreme, and their relatively low costs make their use highly economical. For more extreme wastes like those encountered in the Hanford storage tanks, new titanium-based materials have been developed that are able to withstand the high alkalinity and have sufficiently high selectivity to remove trace levels of strontium in the presence of molar quantities of other ions. Although these synthetic exchangers cost hundreds of US dollars per kilogram, their extreme selectivity and ability to be regenerated makes them viable options for the treatment of these extremely complex wastes.

Acknowledgements

I would particularly like to acknowledge Professor Abraham Clearfield, Dr. Elizabeth Bluhm and Gina Graziano at Texas A&M University, who worked with me on the titanate and titanasilicate ion exchange materials.

Because sugar derivatives are generally present as complex mixtures, chromatographic techniques are crucial in their analysis. The spectrophotometric methods, and other methods mentioned in this article, serve primarily as chromatographic detection

systems, and spectroscopic methods are frequently used in conjunction with chromatography.

Detection Reagents for Planar Chromatography and for Qualitative and Spot Tests

Detection reagents that are specific for particular derivatives, or can distinguish certain classes from

others, are listed in Table 1, which also shows the colours produced in each case and, where known, the detection limit. These reagents are used in spot tests and as detection reagents in planar chromatography, those not containing corrosive acids being applicable to both paper and thin-layer chromatography.

Gas Chromatography

Some sugar derivatives are sufficiently volatile to be analysed by gas chromatography (GC) without further derivatization; this particularly applies to the partially methylated methyl glycosides and methyl glycoside methyl esters produced by methanolysis of methylated polysaccharides. Multiple peaks, corresponding to α and β anomers of pyranoside and furanoside forms, are given by each glycoside, a factor that complicates analysis but can aid the identification of the individual components of simple, well-resolved mixtures. Unsubstituted methyl glycosides require derivatization for analysis by GC; they are successfully analysed as either trimethylsilyl (TMS) ethers or trifluoroacetyl (TFA) esters. Here again the characteristic patterns of multiple peaks produced can facilitate identification. However, for analysis of complex mixtures it is desirable to simplify the chromatogram by elimination of the anomeric centre.

The mixtures of partially methylated sugars obtained in methylation analysis of polysaccharides are usually submitted to GC as the acetylated alditol derivatives, for which a large body of mass spectrometry (MS) data is available. However, for some carbohydrates, notably amino- and acetamidodeoxy sugars, the GC retention times of the derived alditol acetates are excessively long. For aminodeoxyhexoses this problem can be overcome by nitrous acid deamination of the amino sugars before reduction and acetylation, or by *N*-methylation of the aminodeoxyalditols prior to acetylation. The most satisfactory procedure in the analysis of the mixtures of sugars obtained on hydrolysis of bacterial cell wall polysaccharides or glycoconjugates is derivatization to *O*-methyloximes, followed by acetylation or trimethylsilylation. No more than two peaks are produced by each component of the mixture and simultaneous analysis of neutral and amino sugars, as well as *N*-acetylneuraminic acid, muramic acid and its *N*-acetyl derivative and 3-deoxy-*D*-manno-2-octulosonic acid (KDO), within 40 min is possible by capillary GC as the acetylated *O*-methyloximes.

GC analysis of uronic acids also requires derivatization by specific methods if the multiple peaks given by methyl glycoside methyl esters or TMS ethers are to be avoided. Conversion to the oxime is an option in this case too, or the acids may be reduced to

aldonic acids (by sodium borohydride reduction of the alduronates) and analysed as the TMS derivatives of the aldono-lactones or the acetylated derivatives of the *N*-alkylaldonamides produced on reaction of the aldono-lactones with a *L*-alkylamine in pyridine. Both methods of derivatization proceeding via the aldonic acids result in the production of a single GC peak for each uronic acid present. The latter method has the advantage that simultaneous analysis of aldoses, as the alditol acetates, is possible – the alditol acetates have much shorter retention times than the *N*-alkylaldonamide acetates. Complete analysis of neutral and acidic sugars within 20 min is possible by capillary GC of these derivatives.

Oligosaccharide-alditols, up to tetrasaccharide level, can be analysed by GC as their permethylated derivatives. The volatility of those containing acetamidodeoxyhexose residues can be increased by *N*-trifluoroacetylation of these residues (through transamidation by trifluoroacetylation under carefully controlled conditions) prior to methylation. This procedure permits GC analysis of oligosaccharide-alditols containing up to seven sugar residues and also allows the use of the electron capture detector, with a hundredfold increase in sensitivity.

Recommended conditions for GC analysis of various sugar derivatives are listed in Table 2. Comprehensive retention data are available in the literature.

Liquid Chromatography

Carbohydrate derivatives can be analysed by liquid chromatography (LC) in various modes, depending on the polarity of the molecule and whether acidic or basic groups are present. Nonpolar compounds, or those rendered nonpolar by derivatization to increase the sensitivity of analysis, are amenable to reversed-phase LC or adsorption chromatography on silica. For hydroxylic compounds such as alditols, several options are available, including normal-phase LC on bonded amino phases or amine-modified silica (the column packing being modified *in situ* by addition of a polyfunctional amine to the mobile phase); LC on a cation exchange resin in the Ca^{2+} form (ion-moderated partitioning) or, as borate complexes, on an anion exchange resin; and ion chromatography, with pulsed amperometric detection. Recently, cyclodextrin-bonded silica has also proved effective.

The oligosaccharide-alditols obtained in degradative structural studies of glycoproteins can also be analysed by LC in various ways; normal-phase LC, ion exchange, ion chromatography and size exclusion chromatography. Amino- and acetamidodeoxyhexoses and the hexitols derived from them can be analysed by normal-phase LC; ion-moderated

Table 1 Reagents used in qualitative analysis for detection of sugar derivatives

<i>Derivatives</i>	<i>Reagent mixture</i>	<i>Procedure</i>	<i>Colour produced</i>
Alditols and cyclitols	<p>Fluor's reagent:</p> <p>(a) HgO (5%, m/v) in HNO₃ (5%, m/v), diluted 1 : 1 before use</p> <p>(b) Barium acetate (10%, m/v) mixed 1 : 10 with glacial acetic acid</p> <p>Periodate-<i>p</i>-anisidine:</p> <p>(a) <i>p</i>-Anisidine (1%, m/v) in ethanol (70%, v/v)</p> <p>(b) NaIO₄ (0.1 mol L⁻¹ aqueous solution) mixed 1 : 10 with acetone</p> <p>Vanillin-perchloric acid:</p> <p>(a) Vanillin (1%, m/v) in ethanol</p> <p>(b) HClO₄ (3% aqueous solution). Table 1 Continued

Derivatives	Reagent mixture	Procedure	Colour produced
Methyl ethers and methyl esters	<i>p</i> -Anisidine hydrochloride 3% (m/v) solution in 1-butanol	Spray; heat at 110°C for 10 min	Methyl ethers give highly characteristic pink, red or brown spots, some fluorescent under UV. Methyl esters of methylated uronic acids give bright pink colour
Neuraminic acids	Resorcinol-HCl-Cu(II) (a) Resorcinol (0.2%, m/v) in 4 mol L ⁻¹ HCl (b) Aqueous solution of CuSO ₄ · 5H ₂ O (0.1 mol L ⁻¹). Mix (a) and (b) (40 : 1) at least 4 h before use Periodate-thiobarbiturate (a) NaIO ₄ (0.5 mol L ⁻¹) in 0.025 mol L ⁻¹ H ₂ SO ₄ (b) Ethylene glycol-aetone-conc. H ₂ SO ₄ (50 : 50 : 0.3 v/v/v) (c) Sodium 2-thiobarbiturate, 6% (m/v) in H ₂ O	Spray; heat at 110–120°C for about 20 min Spray with (a); leave at room temperature for 15 min; dry thoroughly in stream of air; spray with (b); dry similarly. If odour of formaldehyde persists spray again with (b). Finally, spray with (c); heat at 100°C for 10 min	Neuraminic acids give blue spots; ketoses also react Only neuraminic acids give red spots (detection limit about 3 µg)
Phosphates	Ammonium molybdate 10% (m/v) aqueous solution (20 mL) added to conc. HCl (3 mL) with shaking; NH ₄ Cl (5 g) added	Spray	Phosphorylated derivatives give immediate yellow colour of ammonium phosphomolybdate
Uronic acids	<i>p</i> -Anisidine hydrochloride See above Periodate- <i>p</i> -anisidine See above Mixed indicators Thymol blue (0.025%, m/v) and bromothymol blue (0.06%, m/v) in 95% ethanol; 1 mol L ⁻¹ NaOH added until blue-green colour reached	See above See above Spray	Red spots; do not fluoresce under UV Red spots on brown background; do not fluoresce (distinction from spots given by neutral sugars) Uronic acids and oligomers (e.g. oligogalacturonic acids) give red spots on green background

Table 2 Continued

Compounds	Derivatives for GC	Column type	Phase	Temperature (°C)	Gas; flow rate (mL min ⁻¹)
Methyl glycosides, methylated	Run as such	Packed	Ethylene glycol succinate, polyester, 14% on Chromosorb W (80–100 mesh)	155	He; 40
Muramic acid, KDO and neuraminic acid derivatives	O-Methylloximes, acetylated	Capillary	OV-1	175°C (4 min); 175 → 260°C at 4°C min ⁻¹ ; 260°C (5 min)	He; 0.5
Oligosaccharide-alditols	Permethylated	Packed	Dexsil 300, 1% on Supelcoport (100–120 mesh)	150 → 320°C at 4°C min ⁻¹	He; 40
	Permethylated, N-trifluoroacetylated	Capillary	OV-101	200°C (2 min); 200 → 350°C at 4°C min ⁻¹	He; 0.8
Uronic acids	Methyl glycoside methyl esters, trimethylsilylated	Capillary (fused silica)	CP-Sil 5	140°C (2 min); 140 → 260°C at 8°C min ⁻¹	He; 1
	O-Methylloximes, trimethylsilylated	Capillary (fused silica)	DB-5 (bonded phase)	150 → 220°C at 2°C min ⁻¹	N ₂ ; 1
	Aldonolactones, trimethylsilylated	Capillary (fused silica)	SP-2100	180	He; 1
	N-Alkylaldonamides, acetylated	Packed	OV-1 or OV-17, 0.5% on Chromosorb G (100–120 mesh)	160	N ₂ ; 30
		Capillary	SP-2340, 3% on Supelcoport (100–120 mesh)	190 → 260°C at 5°C min ⁻¹	He; 20
		Capillary	SP-2330	200°C (2 min); 200 → 235°C at 3°C min ⁻¹ ; 235°C (5 min)	He; 10
		Capillary (fused silica)	DB-1701 (bonded phase)	220 → 270°C at 1°C min ⁻¹	He; 12

partitioning on a cation exchange resin with an aqueous-organic solvent system as eluent; cation exchange chromatography; or ion chromatography. Uronic acids, on the other hand, are best analysed by anion exchange chromatography or ion-moderated partitioning on a cation exchange resin in the H^+ form. The same applies to aldonic acids and aldolactones. Oligogalacturonic acids are similarly analysed, but ion chromatography and ion pair chromatography (with the tetrabutylammonium cation in the mobile phase) are further options in this case. The ion pair method has been applied to both normal oligogalacturonic acids and the unsaturated products (with 4,5-unsaturated residues at their non-reducing termini) given on digestion of pectic acid with *endo*-polygalacturonic acid lyase. The unsaturated acids obtained on lyase digestion of glycosaminoglycuronans can also be analysed by this method, as well as by anion exchange chromatography and ion-moderated partitioning on a cation exchange resin with an aqueous-organic solvent system.

The various LC systems applicable to analysis of carbohydrate derivatives are listed in Table 3. Retention data have been published elsewhere.

Electrochemical Methods Linked to LC

The pulsed amperometric detector, in which analytes are oxidized at the surface of a gold electrode, a selected potential being applied between this and a silver/silver chloride reference electrode, with a glassy carbon counterelectrode maintaining the potential without excessive drain on the reference electrode, has proved highly successful when applied in ion chromatography of carbohydrates at high pH (≥ 12). Not only neutral sugars but also alditols, amino- and acetamidodeoxyhexoses, neuraminic acid derivatives and uronic acids can be analysed in this way. If the concentration of NaOH in the eluent is too low for optimal response of the detector, post-column addition of NaOH at higher concentration is required; an example of this is the analysis of amino- and acetamidodeoxyhexoses, which are best resolved with eluents containing 10–15 mmol L^{-1} sodium hydroxide, but are only detected satisfactorily after addition of 0.3 mol L^{-1} sodium hydroxide to the column effluent. The method is applicable to oligosaccharides, including the complex series, neutral, sialylated or phosphorylated, derived from glycoconjugates, and is now extensively used in analysis of such oligosaccharides.

It is only readily oxidizable compounds that can be analysed by oxidation at the surface of a glassy carbon electrode, and this permits the determination of L-ascorbic acid in the presence of other carbohydrates

that are not electroactive with this electrode. Examples include the analysis of algal extracts for L-ascorbic acid and its C5 diastereoisomer, D-erythorbic acid, at nanogram levels, after LC on a microparticulate cation exchange resin (H^+ form), eluted with 0.1 mol L^{-1} formic acid; co-eluting reducing sugars and lactones do not interfere when the carbon electrode is used as a detector. The use of this electrochemical detector has also proved invaluable in the determination of L-ascorbic acid in beers, to which it is added as an antioxidant; in a recommended procedure the glassy carbon electrode is used as a detector in LC of the beer samples on C_{18} -silica, eluted with a citrate buffer (pH 4.4) containing N-methyldodecylamine (1 mmol L^{-1}) as an ion-pairing reagent. The detection limit for ascorbic acid is about 1 ng.

Conductivity detectors can be used in the analysis of charged molecules. An example is afforded by the simultaneous determination of inositol phosphates, sugar phosphates and aliphatic organic anions such as pyruvate, lactate and citrate in physiological samples (rat brain and liver) by ion chromatography with conductivity detection. A post-column micromembrane suppressor, continually regenerated with dilute sulfuric acid, replaces the sodium ions in the eluent ($NaHCO_3$ – Na_2CO_3 ; see Table 3) with hydrogen ions, thus removing the eluent anions by conversion to carbon dioxide and water. This method permits detection of phosphates in the range 20–100 pmol.

Supercritical Fluid Chromatography

Carbon dioxide, widely regarded as the most useful mobile phase for supercritical fluid chromatography (SFC) is a poor solvent for polar solutes and those having high molecular mass. For this reason such solutes require derivatization to nonpolar products before analysis by SFC is possible. In the carbohydrate field the main successes of the method have been its application to series of homologous oligosaccharides, such as the maltodextrins, as their permethylated or trimethylsilylated derivatives, and to permethylated glycoconjugates. Coupled to chemical ionization mass spectrometry (CI-MS), SFC affords a sensitive analytical method (with detection limits at the picomole level) in such applications as monitoring of degradation of polysaccharides (e.g. starch) and profiling of glycoconjugates. With ammonia as the reactant gas for CI-MS, selected-ion monitoring of the $[M + NH_4]^+$ ions as the analytes emerge from the SFC column permits sensitive detection of derivatized glucooligosaccharides to a degree of polymerization (DP) of 15 and above; for the glycoconjugate derivatives the molecular mass limit is not in

Table 3 LC systems applicable to analysis of carbohydrate derivatives

Compounds	Column packing	Mobile phase	Temperature (°C)	Detection system
Acetates	Silica	<i>n</i> -Hexane-acetone (10 : 1) or <i>n</i> -hexane-ethyl acetate (1 : 1)	RT	RI or UV
Acetylated oligosaccharides (to DP 30–35)	C ₁₈ -silica	Acetonitrile–water, linear gradient, 10 → 70% acetonitrile (80 min)	65	UV
Alditols	NH ₂ -silica	Acetonitrile–water (4 : 1)	RT	RI
	Amine-modified silica (impregnated with tetraethylenepentamine)	Acetonitrile–water (3 : 1), containing tetraethylenepentamine (0.02%)	RT	RI
	Cyclodextrin-bonded silica	Acetonitrile–water (4 : 1)	RT	RI
	Cation exchange resin (Ca ²⁺ form)	Water	65	RI
	Cation exchange resin (Pb ²⁺ form)	Ethanol–water (1 : 4)	80	RI
	Anion exchange resin (quaternary ammonium type)	0.50 mol L ⁻¹ borate buffer, pH 7.1 (35 min) 0.35 mol L ⁻¹ borate buffer, pH 8.1 (30 min) 0.50 mol L ⁻¹ borate buffer, pH 10.5 (25 min)	65	Photometric or fluorimetric automated periodate–petane-2,4-dione method
	Pellicular anion exchanger used in ion chromatography	0.15 mol L ⁻¹ NaOH	RT	Pulsed amperometric
Aldonic and aldaric acids	Cation exchange resin (H ⁺ form)	4.5 mmol L ⁻¹ H ₂ SO ₄	25	UV
	Anion exchange resin (quaternary ammonium type)	0.2 mol L ⁻¹ ammonium formate, pH 3.2 For aldaric acids: 0.16 mol L ⁻¹ NaCl containing MgCl ₂ (20 mmol L ⁻¹)	45 85	UV UV
Amino and acetamidodeoxy-hexoses and -hexitols	NH ₂ -silica	Acetonitrile–0.15 mmol L ⁻¹ phosphate buffer, pH 5.2 (4 : 1)	RT	UV
	Cation exchange resin (H ⁺ form)	Acetonitrile–water (23 : 2)	30	UV, automated 2-cyanoacetamide method
	Cation exchange resin (Na ⁺ form) used in amino acid analyser	0.1 mol L ⁻¹ sodium citrate, pH 7.2 20 mmol L ⁻¹ Na ₂ B ₄ O ₇ , pH 8.0	40 (15 min); 63 (45 min) 60	Photometric, automated ninhydrin method Fluorimetric, automated <i>o</i> -phthalaldehyde method
	Pellicular anion exchanger used in ion chromatography	10 mmol L ⁻¹ NaOH; post-column addition of 0.3 mol L ⁻¹ NaOH to raise pH to optimum for detection method	RT	Pulsed amperometric detector
As benzoylated hexitols	Silica	<i>n</i> -Hexane-dioxane-dichloromethane, linear gradient, 22 : 2 : 1 → 4 : 2 : 1 (80 min)	RT	UV
As pyridylamino derivatives	C ₁₈ -silica	0.25 mol L ⁻¹ sodium citrate buffer, pH 4.0, containing acetonitrile (1.0%)	RT	Fluorimetric

Table 3 Continued

Compounds	Column packing	Mobile phase	Temperature (°C)	Detection system
Ascorbic acid	Cation exchange resin (H ⁺ form)	4.5 mmol L ⁻¹ H ₂ SO ₄ or 0.1 mol L ⁻¹ HCOOH	25	UV
	C ₁₈ -silica	25 mmol L ⁻¹ sodium citrate buffer, pH 4.4, containing <i>N</i> -methyldecylamine (1 mmol L ⁻¹)	30 RT	Amperometric (glassy carbon electrode) Amperometric, as above
Cyclitols	Amine-modified silica (impregnated with tetraethylenepentamine) Cation exchange resin (Ca ²⁺ form)	Acetonitrile–water (3 : 1), containing tetraethylenepentamine (0.02%) Water	RT 85	RI RI
Gangliosides	NH ₂ -silica	(A) Acetonitrile–5 mmol L ⁻¹ phosphate buffer, pH 5.6 (83 : 17) (B) Acetonitrile–20 mmol L ⁻¹ phosphate buffer, pH 5.6 (1 : 1) Gradient elution: Solution A (7 min); A → A + B (33 : 17) in 53 min; → A + B (9 : 16) in 20 min	RT	UV
Benzoylated	Silica	<i>n</i> -Hexane–dioxane, linear gradient, 7 → 23% dioxane (18 min)	RT	UV
Glycolipids, benzoylated	Silica	<i>n</i> -Hexane–dioxane, linear gradient, 2.5 → 25% dioxane (13 min); isocratic (5 min)	RT	UV
Glycosides, methyl	Silica C ₁₈ -silica Cation exchange resin (Ca ²⁺ form)	Acetonitrile–water (9 : 1) Water Water	RT RT 1.5	RI RI RI
Benzoylated	C ₁₈ -silica	Acetonitrile–water, linear gradient, 35 → 90% acetonitrile (65 min)	RT	UV
Glycosides, other Acetylated	Silica	Benzene–ethyl acetate (9 : 1) For aryl glycosides: Chloroform–carbon tetrachloride (3 : 2) Methanol–water (13 : 7)	RT	UV
Benzoylated	C ₁₈ -silica Silica	Benzene–ethyl acetate (99 : 1)	RT	UV
Lactones	Cation exchange resin (H ⁺ form)	4.5 mmol L ⁻¹ H ₂ SO ₄	25	UV
Methyl ethers, as alditols	C ₁₈ -silica	Water–acetonitrile (99 : 1)	RT	RI

Table 3 Continued

Compounds	Column packing	Mobile phase	Temperature (°C)	Detection system
Neuraminic acid derivatives, KDO and derivatives	Anion exchange resin (quaternary ammonium type)	0.75 mmol L ⁻¹ Na ₂ SO ₄ For KDO disaccharides: 10 mmol L ⁻¹ Na ₂ SO ₄	RT	UV
Neuraminic acids, DDB derivatives	C ₁₈ -silica	Water-methanol-acetonitrile (77 : 15 : 8)	RT	Fluorimetric
Oligogalacturonic acids, to DP 10	Cation exchange resin (H ⁺ form)	5 mmol L ⁻¹ H ₂ SO ₄	85	RI
DP 5-20	Pellicular anion exchanger used in ion chromatography	0.15 mol L ⁻¹ NaOH, with sodium acetate, gradient: 0.40 mol L ⁻¹ (2 min); 0.40 → 0.90 mol L ⁻¹ (43 min)	RT	Pulsed amperometric
Oligosaccharides, chitin, to DP 5	NH ₂ -silica	Acetonitrile-water (7 : 3)	25	RI
Oligosaccharides, from glycoproteins	NH ₂ -silica	Acetonitrile-15 mmol L ⁻¹ phosphate buffer, pH 5.2 (4 : 1); isocratic (30 min); buffer 20 → 45% (50 min)	RT	UV
		For higher oligosaccharides : (8-12 sugar residues): Linear gradient: buffer 20 → 44% (80 min)		
	Pellicular anion exchanger used in ion chromatography	For neutral oligosaccharides: (2-11 sugar residues): (A) 0.10 mol L ⁻¹ NaOH (B) 0.10 mol L ⁻¹ NaOH containing sodium acetate (0.15 mol L ⁻¹)	RT	Pulsed amperometric
		Gradient elution: A (10 min) A → A + B (1 : 4) in 60 min Post-column addition of 0.3 mol L ⁻¹ NaOH to raise pH for detection method For sialylated oligosaccharides (3-8 sugar residues): 50 mmol L ⁻¹ NaOH containing 100 mmol L ⁻¹ sodium acetate		
Oligosaccharides (2-8 residues), from hyaluronic acid	NH ₂ -silica	0.1 mol L ⁻¹ KH ₂ PO ₄ , pH 4.75	RT	UV
Oligosaccharide-alditols, from glycoproteins, 2-7 residues	NH ₂ -silica	Acetonitrile-1 mmol L ⁻¹ KH ₂ PO ₄ , pH 5.4 (3 : 2)	RT	UV
2-20 residues	Size exclusion chromatography packing	Water	55	RI or scintillation counting after labelling with ³ H

Table 3 Continued

Compounds	Column packing	Mobile phase	Temperature (°C)	Detection system
Oligosaccharide-alditols, ethylated and methylated (2–6 residues)	C ₁₈ -silica	Acetonitrile–water, various proportions from 1 : 1 to 3 : 2, or linear gradient, 50 → 65% acetonitrile (45 min)	RT	RI, MS
Oligosaccharides, pyridylamino derivatives (2–20 residues)	Two-dimensional mapping: (1) C ₁₈ -silica (2) NH ₂ -silica	For column 1: (A) 10 mmol L ⁻¹ phosphate buffer, pH 3.8; (B) A containing 1-butanol (0.5%) Linear gradient, 20 → 50% B (60 min) For column 2: (C) Acetonitrile–3% acetic acid in water containing triethylamine, pH 7.3 (13 : 7) (D) As C, but proportions 1 : 1 Linear gradient, C → D (50 min)	55 40	Fluorimetric Fluorimetric
Phosphates	Pellicular anion exchanger used in ion chromatography C ₁₈ -silica	2.4 mmol L ⁻¹ NaHCO ₃ –1.92 mmol L ⁻¹ Na ₂ CO ₃ For monophosphates: 20 mmol L ⁻¹ HCOOH, containing tetrabutylammonium hydroxide (8 mmol L ⁻¹) as ion-pairing reagent and Eu complex (0.02 mmol L ⁻¹) as detection reagent For diphosphates: 20 mmol L ⁻¹ HCOOH–20 mmol L ⁻¹ HCl–40 mmol L ⁻¹ NaCl; concentration of tetrabutylammonium hydroxide increased to 30 mmol L ⁻¹ , that of Eu complex unchanged	RT 38	Conductivity anion micromembrane suppressor UV photometry of adduct with Eu complex
Phosphorylated oligosaccharides (2–5 sugar residues)	Pellicular anion exchanger used in ion chromatography	0.1 mol L ⁻¹ NaOH (5 min); linear acetate gradient, 0 → 0.6 mol L ⁻¹ sodium acetate in 0.1 mol L ⁻¹ NaOH (67 min); isocratic (5 min)	RT	Pulsed amperometric
Unsaturated oligosaccharides (2–7 residues), from lyase digestion of:				
Alginate	C ₁₈ -silica	Acetonitrile–0.1 mol L ⁻¹ phosphate buffer, pH 6.5 (1 : 9), containing tetrabutylammonium hydroxide (10 mmol L ⁻¹)	RT	UV

Table 3 Continued

Compounds	Column packing	Mobile phase	Temperature (°C)	Detection system
Pectic acid	C ₁₈ -silica	Methanol-0.05 mol L ⁻¹ phosphate buffer, pH 7.0 (3 : 7), containing tetrabutylammonium bromide (25 mmol L ⁻¹)	40	UV
	Anion exchanger (quaternary ammonium) bonded to silica	0.4 mol L ⁻¹ sodium acetate buffer, pH 5.4	40	UV
Hyaluronic acid	C ₁₈ -silica	(A) Acetonitrile-8 mmol L ⁻¹ H ₃ PO ₄ (1 : 4), pH of mixture 7.6; contains tetrabutylammonium hydroxide (10 mmol L ⁻¹) (B) Acetonitrile-6 mmol L ⁻¹ H ₃ PO ₄ (3 : 2), pH of mixture 7.5; concentration of ion-pairing reagent as in A	RT	UV
		Linear gradient, A → A + B (19 : 1) in 18 min	RT	UV
Unsaturated sulfated oligosaccharides, from lyase digestion of glycosamino-glyronans	Anion exchanger (quaternary ammonium) bonded to silica	For oligosaccharides to hexasaccharide: Linear gradient, 0.2 → 0.8 mol L ⁻¹ NaCl, pH 3.5 (50 min)	RT	UV
	NH ₂ -silica	Disaccharides only: 10 mmol L ⁻¹ Na ₂ SO ₄ -1 mmol L ⁻¹ CH ₃ COOH	50	UV
	Cation exchange resin (Na ⁺ form)	Disaccharides only: Acetonitrile-methanol-0.8 mol L ⁻¹ ammonium formate buffer, pH 4.5 (13 : 3 : 4)	70	UV
Uronic acids	Cation exchange resin (H ⁺ form)	4.5 mmol L ⁻¹ H ₂ SO ₄	25	UV
	Anion exchanger (quaternary ammonium) bonded to silica	5 mmol L ⁻¹ KH ₂ PO ₄ (pH 4.6) containing methanol (5%)	RT	UV
		0.7 mol L ⁻¹ CH ₃ COOH	40	RI

RT, Room temperature; RI, refractive index.

Table 4 Solvent systems useful in TLC and paper chromatography of sugar derivatives

<i>Derivatives</i>	<i>Stationary phase</i>	<i>Solvent system^a</i>
Acetals and ketals	Silica gel	Benzene-ethanol (2 : 1) Benzene-acetic acid-ethanol (2 : 2 : 1) For pyruvate: Ethyl acetate-acetic acid-formic acid-water (12 : 3 : 1 : 4) (threefold development) Acetonitrile-water (9 : 1)
Acetates	HPTLC plates with bonded aminopropyl phase, impregnated with NaH ₂ PO ₄ (0.2 mol L ⁻¹) Silica gel	 Benzene-ethyl acetate (7 : 3) Benzene-methanol (9 : 1)
Alditols	Paper Paper impregnated with tungstate (0.15 mol L ⁻¹) CMC paper (La ³⁺ , Ca ²⁺ or Ba ²⁺ forms) Cellulose plates impregnated with tungstate (0.15 mol L ⁻¹) Silica gel impregnated with NaH ₂ PO ₄ (0.5 mol L ⁻¹)	1-Butanol-ethanol-water (4 : 1 : 5), upper layer 2-Butanone-acetic acid-saturated aqueous solution of H ₃ BO ₃ (9 : 1 : 1) Acetone-1-butanol-water (5 : 3 : 2) 1-Butanol-ethanol-water (10 : 1 : 2) Acetone-1-butanol-water (5 : 3 : 2) 2-Propanol-acetone-0.2 mol L ⁻¹ lactic acid (6 : 3 : 1)
Aldonic acids and aldonolactones	Cellulose plates Silica gel, HPTLC	1-Butanol-acetic acid-water (6 : 1 : 2) Ethyl acetate-pyridine-acetic acid-tetrahydrofuran-water (50 : 22 : 4 : 15 : 15)
Amino- and acetamidodeoxyhexoses	Paper Cellulose plates	Ethyl acetate-pyridine-acetic acid-water (5 : 5 : 1 : 3) 1-Butanol-pyridine-benzene-water (5 : 3 : 1 : 3) 1-Butanol-pyridine-0.1 mol L ⁻¹ HCl (5 : 3 : 2) Two-dimensional development: (1) 2-Propanol-90% HCOOH-water (20 : 1 : 5); (2) Lutidine-water (13 : 7) 1-Propanol-water (7 : 1)
Dansyl derivatives	Silica gel	Cyclohexane-ethyl acetate-ethanol (6 : 4 : 3)
Anhydroalditols	Silica gel	1-Butanol-acetone-water (5 : 4 : 1)
Anhydro sugars	Silica gel, HPTLC, impregnated with borate (0.1 mol L ⁻¹) HPTLC plates with bonded aminopropyl phase, impregnated with NaH ₂ PO ₄ (0.2 mol L ⁻¹)	Acetonitrile-water (9 : 1)
Branched-chain sugars (apiose, hamamelose and derivatives)	Paper	1-Butanol-pyridine-acetic acid-water (60 : 40 : 3 : 30) 1-Butanol-ethyl acetate-acetic acid-water (8 : 6 : 5 : 8)
Cyclitols	Paper	Acetone-water (4 : 1)
Gangliosides	Silica gel, HPTLC	Methyl acetate-2-propanol-33 mmol L ⁻¹ KCl (9 : 6 : 4) Acetonitrile-2-propanol-50 mmol L ⁻¹ KCl (10 : 67 : 23)
Glycosides, aryl, acetylated	Silica gel	Acetonitrile-2-propanol-2.5 mol L ⁻¹ aqueous ammonia (2 : 13 : 5) 2-Butanone-light petroleum (1 : 3)

Table 4 Continued

Derivatives	Stationary phase	Solvent system ^a
Glycosides, methyl	Paper	t-Pentanol–1-propanol–water (8 : 2 : 3)
	Cellulose plates	Ethyl acetate–pyridine–acetic acid–water (5 : 5 : 1 : 3)
Methylated	Silica gel	1-Butanol–acetic acid–water (3 : 1 : 1)
		Benzene–ethanol–water (170 : 47 : 15), upper layer
Methyl ethers	Paper	1-Butanol–ethanol–water (4 : 1 : 5), upper layer
		2-Butanone–water azeotrope (85 : 7)
	Cellulose plates	2-Butanone–saturated with water
	Silica gel	2-Butanone–water azeotrope
		Benzene–ethanol–water–aqueous ammonia (200 : 47 : 15 : 1), upper layer
	Silica gel impregnated with H ₃ BO ₃ (0.1 mol L ⁻¹)	1-Butanol–acetone–water (4 : 5 : 1)
Muramic acid (separated from aminodeoxyhexoses)	Cellulose plates	Two-dimensional development : (1) 2-Propanol–90% HCOOH–water (20 : 1 : 5), (2) Lutidine–water (13 : 7) Acetonitrile–ethanol–acetic acid–water (13 : 2 : 1 : 4)
	Silica gel	Methanol–water (5 : 2)
Neuraminic acids, N-acetyl and N-glycolyl	Silica gel	Ethyl acetate–acetic acid–water (2 : 1 : 2), twofold development
Oligogalacturonic acids (to DP 9)	Cellulose plates	Ethanol–25 mmol L ⁻¹ CH ₃ COOH (21 : 29), 35°C
	Silica gel, HPTLC	Acetonitrile–water (18 : 7)
Oligosaccharides, chitin (to DP 6)	HPTLC plates with bonded aminopropyl phase, impregnated with NaH ₂ PO ₄ (0.2 mol L ⁻¹)	
Oligosaccharides, from hyaluronic acid (2–8 residues)	Silica gel	2-Propanol–water (33 : 17), containing NaCl (50 mmol L ⁻¹)
Phosphates	Paper	Methanol–90% HCOOH–water (16 : 3 : 1), containing tetrasodium salt of EDTA (0.05%, m/v)
Unsaturated disaccharides, from lyase digestion of glycosaminoglycuronans, run as dansylhydrazones	Silica gel	1-Propanol–2-propanol–1-butanol–water (6 : 9 : 1 : 4), containing NaCl (40 mmol L ⁻¹) and ammonia (10 mmol L ⁻¹)
Uronic acids and alduronolactones	Paper	1-Butanol–acetic acid–water (2 : 1 : 1)
		Ethyl acetate–acetic acid–formic acid–water (18 : 3 : 1 : 4)
		Ethyl acetate–acetic acid–pyridine–water (10 : 3 : 3 : 2)
		Ethyl acetate–acetic acid–water (3 : 1 : 1)
	DEAE-cellulose paper	1-Butanol–acetic acid–water (6 : 1 : 2)
	Cellulose plates	1-Butanol–ethanol–0.1 mol L ⁻¹ H ₃ PO ₄ (1 : 10 : 5)
	Silica gel impregnated with NaH ₂ PO ₄ (0.3 mol L ⁻¹)	

^aAll proportions are by volume.

Table 5 Lectins used in affinity chromatography of oligosaccharides

Lectin	Specificity
Concanavalin A (Con A)	α -D-Man, terminal or substituted only at O2; terminal β -D-GlcNAc at O2 promotes binding
<i>Datura stramonium</i> agglutinin (DSA)	$[\beta$ -D-Gal (1 \rightarrow 4) β -D-GlcNAc (1 \rightarrow 3)] _n , i.e. poly (<i>N</i> -acetylglucosamine); binds tri- and tetraantennary oligosaccharides lacking this sequence if outer Man residue is substituted at O2 and O6 by <i>N</i> -acetylglucosamine
<i>Griffonia simplicifolia</i>	Terminal α -D-Gal
<i>Helix pomatia</i> (HP)	Terminal α -D-GalNAc
<i>Lens culinaris</i> (lentil)	Terminal α -D-Man: outer Man residue substituted at O2 and O6 by GlcNAc
Phytohaemagglutinin, erythroagglutinating (E ₄ -PHA)	Bisecting GlcNAc at O4 of inner Man residue and sequence β -D-Gal (1 \rightarrow 4) β -D-GlcNAc (1 \rightarrow 2) α -D-Man in outer chains
Phytohaemagglutinin, leukoagglutinating (L ₄ -PHA)	Tri- and tetraantennary oligosaccharides with outer Man residue substituted at O2 and O6 by <i>N</i> -acetylglucosamine
<i>Pisum sativum</i> (pea)	Terminal α -D-Man; α -L-Fuc at O6 of 4-linked GlcNAc in inner core of <i>N</i> -linked oligosaccharide
<i>Ricinus communis</i> agglutinin (RCA-I)	Terminal β -D-Gal
<i>Sambucus nigra</i>	α -NeuAc (2 \rightarrow 6) Gal \gg α -NeuAc (2 \rightarrow 3) Gal
<i>Wisteria floribunda</i>	β -D-GalNAc (1 \rightarrow 4) Gal $>$ α -D-GalNAc (1 \rightarrow 3) Gal and α -D-GalNAc (1 \rightarrow 3) GalNAc: substitution of 4-linked Gal by NeuAc at O3, or of 3-linked Gal by α -L-Fuc at O2 weakens binding

excess of 5000. For these the addition of methanol to the carbon dioxide mobile phase has proved advantageous. Fused-silica microbore capillary columns, with a bonded methylpolysiloxane stationary phase (DB-1 and, especially, DB-5 are very effective), are used at temperatures ranging from 90 to 120°C and with pressure programming over the range 10–40 MPa (100–400 bar) at about 0.5 MPa min⁻¹ (5 bar min⁻¹). Under these conditions there is resolution of α and β anomers (more pronounced with the TMS derivatives) and fine structure is discernible in glycoconjugates.

Thin-Layer Chromatography (TLC) and Paper Chromatography

While nonpolar derivatives can be separated by thin-layer chromatography (TLC) on unmodified silica plates, resolution of polar molecules is generally poor unless the silica gel layer is impregnated beforehand with an inorganic salt capable of interacting with carbohydrates. Borate or phosphate buffers are most

often used for this purpose; tungstate can also prove effective, especially in TLC of alditols. The same applies to TLC on high performance (HP) TLC plates, particularly those carrying a bonded aminopropyl phase, which is liable to react covalently with sugars and derivatives containing hydroxyl groups. Some separations, particularly those of aminodeoxy sugars, that are not well resolved on impregnated silica gel plates, are better on unmodified silica plates. Cellulose plates also give satisfactory resolution of these derivatives, and of neutral sugars and uronic acids, but two-dimensional development is often required. Impregnation of these plates with tungstate greatly improves their resolving power for alditols.

Although paper chromatography has largely been superseded by TLC, there are groups of sugar derivatives that are far better resolved on paper than by TLC methods. The mixtures of partially methylated sugars obtained in methylation analysis of polysaccharides afford a prime example: resolution on cellulose plates is better than that on silica plates but

paper chromatography remains the most effective method. As in the case of TLC, separation of alditols on paper is improved by impregnation of the paper with tungstate. Papers having ion exchange properties can also be used to good effect in separations of some sugar derivatives: uronic acids and aldobiouronic acids are well resolved on DEAE-cellulose paper (anion exchanger), while carboxymethylcellulose paper, converted beforehand to the La^{3+} , Ca^{2+} or Ba^{2+} forms, gives excellent resolution of alditols.

Some solvent systems that have proved effective in TLC and paper chromatography of sugar derivatives are listed in Table 4.

Affinity and Enzyme Methods

Affinity Chromatography

Lectin affinity chromatography is a valuable technique in analyses of glycoconjugates, as the isolation and identification of glycopeptides and the various oligosaccharides obtained on removal of the carbohydrate side chains from the protein or lipid moieties are greatly facilitated by chromatography on a series of short columns, each containing a different lectin covalently coupled to agarose gel. The lectins are selected according to their specificity towards carbohydrates having certain of the main structural features found in the oligosaccharides, and in this way the complex mixture of oligosaccharides can be fractionated according to structure. Some of the lectins that have proved useful in such studies are listed in Table 5, together with their carbohydrate-binding specificities.

The oligosaccharides are usually applied to the lectin columns in phosphate-buffered saline (PBS), pH 7.2, Tris-buffered saline (TBS), pH 8.0, or 10 mmol L^{-1} Tris-HCl buffer, pH 7.5; sodium azide (0.02%, m/v) is added as a preservative and small amounts of calcium, magnesium and manganese chlorides (1 mmol L^{-1}) are essential to the binding action of some lectins, notably concanavalin A. Oligosaccharides that are not bound or are only retarded on the lectin column are eluted with these buffers, but those that are strongly bound require the addition of a competing hapten to the eluent. Haptens applicable to the lectins listed above include methyl α -D-mannopyranoside, lactose, GalNAc, GlcNAc and N,N'-diacetylchitobiose.

A recent development in affinity chromatography is the use of monoclonal antibodies as ligands; these are highly specific but less strongly reactive than lectins, and the dissociation constants of the complexes formed with bound solutes are sufficiently low to permit rapid fractionation, the oligosaccharides reacting

with the ligand being merely retarded on the column, not totally immobilized. An example of the use of this technique is afforded by the complete separation of two of the oligosaccharides of human milk, α -NeuAc(2 \rightarrow 3) β -D-Gal(1 \rightarrow 3) β -D-GlcNAc(1 \rightarrow 3) β -D-Gal(1 \rightarrow 4)Glc (lactosialyltetrasaccharide, LSTa) and that designated sialyl Le^a, which carries α -L-Fuc at O4 of GlcNAc. On a short column containing monoclonal antibody 19.9 coupled to agarose gel, with 10 mmol L^{-1} Tris-HCl buffer, pH 7.5, as eluent, the two oligosaccharides are rapidly separated, the fucosylated sialyl Le^a being the more retarded. The active oligosaccharides of blood group A are similarly fractionated according to chain lengths and degree of fucosylation by chromatography on immobilized IgM antibody, with TBS as eluent. Use of columns in which such antibodies are coupled to microparticulate silica makes possible very rapid separations of oligosaccharides (in 20 min or less). This new technique of high performance liquid affinity chromatography (HPLAC) has great potential in applications such as clinical analysis, for which methods that are highly specific but also efficient are required.

Enzyme Methods

Enzyme methods are particularly useful in analyses of glycoconjugates, for the release of mono- or oligosaccharides that are not easily liberated by acid hydrolysis or are acid-labile, and in the determination of some constituents. The determination of neuraminic acid derivatives in glycoproteins or glycolipids is a striking example of this use of enzymes. The sample (~ 200 μg), dissolved in 60 mmol L^{-1} phosphate buffer (pH 7.0, 800 μL), is incubated at 37°C for 1 h with *Clostridium perfringens* neuraminidase (EC 3.2.1.18) and N-acylneuraminate pyruvate-lyase (EC 4.1.3.3). The former (0.5 U) liberates the neuraminic acid derivatives from glycosidic linkages and the latter (0.3 U) cleaves the molecules to produce N-acyl-mannosamines and pyruvate. The mannosamine derivatives are well separated from GlcNAc, GalNAc and neutral sugar components of glycoconjugates by LC (H^+ form cation exchange resin, 92% acetonitrile in water; see Table 3) and may be determined in this way. Alternatively (or in addition), the proportion of neuraminic acids may be found by determining the pyruvate released, using the definitive lactate dehydrogenase method.

For release of N-linked oligosaccharides from glycoproteins, digestion with N-oligosaccharide glycopeptidase (EC 3.5.1.52) offers a milder alternative to the standard hydrazinolysis procedure. After pepsin digestion of the protein moiety, the product, dissolved in 0.1 mmol L^{-1} citrate-phosphate buffer,

is digested with the glycopeptidase (1 mU per 1000 nmol of oligosaccharides) at 37°C for 15 h. For sequencing purposes, smaller oligosaccharides may be obtained by subsequent digestion with various exoglycosidases, such as α -L-fucosidase (EC 3.2.1.51), β -D-galactosidase (EC 3.2.1.23) and β -N-acetylglucosaminidase (EC 3.2.1.30). The mixtures of oligosaccharides are separated by LC (see Table 3).

Enzyme methods are also important in the analysis of glycosaminoglycuronans, which are very resistant to acid hydrolysis. Hyaluronidase (EC 3.2.1.35) randomly cleaves the (1 \rightarrow 4) bonds linking the acetamidodeoxyhexose residues to glucuronic acid in both hyaluronic acid and the chondroitin sulfates, to yield the disaccharide repeating unit and oligomers. An exception to this is leech hyaluronidase (EC 3.2.1.36), which specifically cleaves the β -D-GlcA (1 \rightarrow 3) β -D-GlcNAc linkages in hyaluronic acid, yielding a different series of oligomers. All of these, including some with odd numbers of sugar residues, obtained by removal of the nonreducing GlcA end-groups with β -glucuronidase (EC 3.2.1.31) or of nonreducing GlcNAc end-groups with β -N-acetylglucosaminidase, are well separated by LC (see Table 3).

A sensitive analytical method for glycosaminoglycuronans is afforded by LC of the unsaturated oligosaccharides produced on digestion with enzymes having lyase activity, which give disaccharides or, in the case of hyaluronic acid, tetra- and hexasaccharides with 4,5-unsaturated residues (4-deoxy-L-threo-hex-4-enopyranosyluronic acid from D-glucuronic acid or L-iduronic acid) at their nonreducing ends. Chondroitinase ABC (EC 4.2.2.4) digests chondroitin 4- and 6-sulfate and dermatan sulfate, whereas chondroitinase AC (EC 4.2.2.5) does not act upon dermatan sulfate, and LC analysis (Table 3) of the mixtures of unsaturated, sulfated disaccharides produced by each enzyme permits quantification of the respective parent glycosaminoglycuronans. Typically, the proteoglycan (1–1000 μ g) is digested at 37°C for 16 h with the enzyme (0.05 U) in Tris buffer (pH 6.0). Hyaluronic acid can be determined specifically by LC analysis of the unsaturated tetra- and hexasaccharide produced on digestion with the lyase from *Streptomyces hyalurolyticus* (H-1136), which cleaves this polymer selectively. Recently the LC profiles of the products of digestion of heparin with heparin lyase (EC 4.2.2.7), from *Flavobacterium heparinum*, have been suggested as a means of characterizing this polydisperse glycosaminoglycuronan: di-, tetra- and hexasaccharides, differing in degree of sulfation and proportion of iduronic acid, are produced, their proportions in the mixture varying with the source of the heparin.

Structural analysis of alginates, which contain blocks of mannuronic acid and guluronic acid residues, all (1 \rightarrow 4) linked, is facilitated by the use of enzymes acting exclusively on one of these acids, leaving intact blocks of the other. These enzymes are lyases, producing unsaturated oligosaccharides from the portions of the polymer that they attack. For example, a β -D-mannuronase has been isolated from actively growing tissues of the seaweed *Sargassum fluitans* and an α -L-gulonase from the bacterium *Klebsiella aerogenes* type 27. Digestion may be monitored by LC analysis of the unsaturated oligosaccharides (Table 3). This applies also to digestion of pectic acid with *endo*-polygalacturonic acid lyase (EC 4.2.2.10). The saturated oligogalacturonic acids produced on digestion of this polymer with *endo*-polygalacturonase (pectinase: EC 3.2.1.15) are also analysed by LC.

Specific Problems: Analysis of Acidic Derivatives

Whereas the enzyme methods discussed above are used in the degradation of glycoproteins and glycolipids, which contain sugar derivatives – such as the neuraminic acid derivatives – that are unstable when heated in acid, and of glycosaminoglycuronans and polyuronans, which are strongly resistant to acid hydrolysis, it is the latter technique that is most widely used to liberate the constituent monosaccharides from other heteropolysaccharides. For those containing aldobiouronic acid linkages, which are far less readily hydrolysed than are glycosidic linkages between neutral sugars, slow release and low yields of both hexuronic acids and the contiguous (interior) sugar residues make quantification difficult. The use of vigorous conditions or prolonged exposure to acid in attempting to improve the yields of these constituents is liable to cause both decarboxylation of the acid and decomposition of some of the neutral sugars already liberated (pentoses being especially vulnerable). For quantitative GC analysis, the difficulty can be obviated by prior reduction of the carboxyl groups in the uronic acid compounds. This is best effected by treatment with a carbodiimide at pH 4.75, followed by reduction with sodium borohydride or borodeuteride at pH 7.0; if the latter is used, the hexoses produced from the hexuronic acids are labelled with deuterium and thus readily identifiable by GC-MS of the derived alditol acetates.

In methylation analysis, the problems posed by resistance to acid hydrolysis of linkages involving methylated uronic acid residues (present as methyl esters) are similar. In this case the recommended procedure is reduction of the carboxylate ester groups

with lithium aluminium deuteride in dry oxolane (tetrahydrofuran) at 70°C for 16 h. The ester residue is then converted to a 6,6-dideuteriohexose residue, the O-methyl ethers of which are easily distinguishable by GC-MS of the derived alditol acetates.

An alternative to acid hydrolysis that is applicable to most polysaccharides and glycoconjugates, including those containing acid-labile residues or glycosidic linkages resistant to hydrolysis, is afforded by methanolysis, in which the sample is heated in methanolic HCl, the conditions employed depending upon the nature of the sugar residues present. After suitable derivatization, all components of methanolysates, now present as methyl glycosides or, in the case of hexuronic acids, methyl glycoside methyl esters, can be analysed simultaneously, either by GC (Table 2) or by LC (Table 3). The procedure is also applicable to methylation analysis, the methylated methyl glycosides and methyl glycoside methyl esters being amenable to GC without further derivatization (Table 2).

SULFUR COMPOUNDS: GAS CHROMATOGRAPHY

W. Wardencki, Technical University of Gdańsk, Gdańsk, Poland

Copyright © 2000 Academic Press

Introduction

Sulfur compounds, of both biogenic and anthropogenic origin, constitute a large group of compounds, ranging from simple gases up to complex polycyclic aromatics. These compounds can be present in various, usually complex matrices, such as air (gaseous), water systems (aqueous), various petroleum fractions (gaseous, liquid and solid), in beverages and food-stuffs and in pharmaceutical formulations.

Environmentalists believe that these compounds are responsible for the damage of our environment through acid deposition, rapid acidification of lakes,

the loss of forests, the corrosion of metal structures and historical monuments. The interest in biogeochemistry results from the role some sulfur compounds play in global chemical cycles. Dimethyl sulfide (DMS) in sea water, produced in the oceans, is believed to play a critical role in the global sulfur cycle and the radiation balance of the Earth. Also, other sulfur compounds may contribute significantly to the sulfur flux in the atmosphere. In foods, beverages and in water, trace levels of sulfur-containing compounds are responsible for taste and odour problems. They are also the source of malodorous conditions in municipal sewage systems. Refiners worldwide give particular attention to these compounds because in petrochemical and chemical applications even trace levels of sulfur impurities may cause concern. They can poison the catalysts, impart

undesirable properties to final products or produce general air pollution when fuel is burnt.

For these reasons sulfur-containing compounds are of constant concern in many fields. Gas chromatography, due to combination of separation capability and sensitive detection is still a prime technique for the analysis of these compounds in various matrices.

General Problems of the Determination of Sulfur Compounds by Gas Chromatography

The analysis of sulfur compounds in different environmental matrices is still a big challenge for the analytical chemist. The main difficulties in their determinations are related to the two main obstacles.

The first is common with general problems encountered in trace analysis. Most of these compounds are present at low concentrations, frequently at the low parts per trillion (ppt) level. They may be encountered in very complex matrices and in a broad range of concentrations (often several orders of magnitude). Complex mixtures can cause interference problems between major and minor constituents.

The second difficulty is due to the highly reactive nature of sulfur compounds. It is well known that these compounds have absorptive, adsorptive, photo-oxidative and metal catalytic oxidative features. This can lead to irreversible adsorption, reaction with each other, catalytic reactions, rearrangements catalysed by different materials and reactions with substances they come into contact with. Because of these reasons special precautions should be undertaken during all steps of their analysis, e.g., during sample treatment (sampling, storage, pre-concentration and isolation) as well as during the gas chromatographic analysis.

When sulfur content is relatively high (up to percentage level) and the matrix is very complex, like crude oil, direct GC analysis can be frequently done, reducing the analysis time and eliminating the possibility of analyte losses. Such samples, due to possible interference problems, require very effective separation systems and very selective (specific) detectors. The choice of a detector with high selectivity for sulfur over hydrocarbon is crucial.

Due to the diversity of the matrices in which sulfur compounds can be present it is convenient to discuss each type of sample separately.

Atmospheric Sulfur Gases

Sulfur gases are released into the atmosphere from various natural and anthropogenic sources. The most abundant atmospheric sulfur compounds are: hydro-

gen sulfide (H_2S), carbonyl sulfide (COS), dimethyl sulfide (DMS), dimethyldisulfide (DMDS), carbon disulfide (CS_2) and methanethiol (methyl mercaptan – MeSH). These compounds have received a great deal of attention because of the suggestion that the emission of natural compounds may be substantial even compared to anthropogenic sources of sulfur dioxide (SO_2). Frequently, all these compounds are called ‘reduced sulfur compounds’, S(-II), abbreviated to RSCs. These compounds, together with other sulfur species with boiling points up to ca. 200°C , are usually termed ‘volatile sulfur compounds’ (VSCs). Considering VSCs the emphasis is especially put on DMS, which is the predominant form of volatile sulfur compounds in the oceans.

Sampling

Sampling vessels (glass bottles, bulbs, canisters and polymeric bags) for sulfur gases should be as inert as possible in order to minimize adsorption losses and to avoid possible reactions during sampling. For these reasons, all materials in sampling vessels, tubing and unions in contact with the sample should be carefully chosen. The conditioning or covering of surfaces with inert materials or application of surface deactivation procedures such as silanization is usually necessary.

Glass sampling bottles or bulbs are commonly used for collecting and transporting gas samples or to blend calibration gas mixtures. Stainless steel canisters and Teflon bottles are very convenient. Frequently, the canisters are conditioned by heating under vacuum before use. Sampling bags made of Tedlar film which is a polyvinyl fluoride (PVF) are chosen because of their inertness. To prevent losses of sulfur compounds, sampling vessels and connections may be covered with aluminium foil to avoid photo-chemical reactions.

Preconcentration

Due to the low concentration of sulfur species in air (ppb or ppt level) different preconcentration techniques have been applied before the gas chromatographic analysis proper. The most frequently used methods for these purposes are sorption on certain metals, sorption on solid sorbents and cryogenic trapping.

Sorption on metals This pre-concentration method is based on the ability of certain metals (mainly gold, palladium and platinum) to chemisorb sulfur gases. Glass or quartz tubes filled with gold wool, gold-coated glass beads, gold-plated sand or metal foils are used for this purpose. The sample may be passed through a Teflon tube containing a thin metal foil of

palladium (Pd), platinum (Pt) or gold (Au). Custom-fabricated Pd on Pt has the advantage of the analytical collection efficiency of Pd and an increased durability and lifetime. Rapid desorption of the sulfur compounds is achieved by passing a current through the foil. Such a technique (metal foil collection/flash desorption and flame photometric detection) has demonstrated a detection limit for total sulfur concentration of around 10 pptv (10^{-11}).

Sorption on solid sorbents Adsorption on solid sorbents is one of the simplest and most efficient methods of concentration of volatile compounds. Adsorbent trapping is very popular, especially when traps are kept at low temperatures. Ambient temperature trapping may frequently give poor recoveries due to poor collection efficiency.

Many sorbents, such as activated charcoal, silica gel, aluminium oxide, graphitized carbon black, molecular sieves and porous polymers have been applied to collect volatile sulfur species. The use of porous polymers is the most widespread since the collected substances can be desorbed from porous polymers more easily, compared to desorption from charcoal. Furthermore, collection efficiency on porous polymers is less sensitive to water vapour in the sampling atmosphere. The trapped compounds are usually released by thermal desorption and injected into a GC column. Before this operation, they may be subjected to cryothermal focussing in a capillary in order to obtain a narrow injection band.

Among the porous sorbents, Tenax has the highest popularity. Tenax has a low affinity for water, and breakthrough volume is relatively independent of humidity. It is well suited for thermal desorption techniques as it exhibits high thermal stability (375°C) and can be subjected to repeated temperature cycling without deterioration. The determination of several sulfur gases can be easily conducted, even though Tenax has a relatively low specific surface area (ca. $19\text{ m}^2/\text{g}$) which consequently limits the sampling volume. In practice, Tenax GC or TA is used together with Chromosorb 106 and Sphercarb as backup adsorbents. In order to retain the low boiling organic sulfur compounds that are present in many samples, cooling the trap with liquid nitrogen may be necessary but this creates a problem when excessive amounts of methane are present. Cooling with solid carbon dioxide is suitable for trapping of VOS compounds under these circumstances. Carbosieve adsorption tubes can be used for collecting CS_2 after purging it from seawater samples.

For moist air samples (96% relative humidity) acceptable recoveries have been observed for the following sorbents: silica gel (recovery for MeSH

> 95%), molecular sieve (recovery for MeSH 73.9% for COS 75%) and Carbosieve III S (recovery for COS 71.7%) used with calcium chloride as a drying agent. For methanethiol, recovery values showed no significant changes during 36 h storage or using different flow rates in the range of $10\text{--}80\text{ mL min}^{-1}$.

Cryogenic trapping Cryogenic trapping is the technique of choice for collecting VSCs from air samples but is not always practical due to transportation and storage difficulties at remote locations.

Cryogenic trapping is very popular after purging VSCs from various water samples and therefore is also discussed in the next section.

Analysis of VSCs in air is complicated by the oxygen, SO_2 and NO_2 which can cause variable and often severe sampling losses by oxidation of these compounds. Scrubbers for oxidant removal include Teflon and Tygon shavings, and various substrates (glass fibre filters, Chromosorb, Anakrom, and glass beads) coated with Na_2CO_3 or manganous oxide, MnO .

Sulfur Compounds in Aqueous Matrices

Sampling

Aqueous samples for the analysis of VSCs are usually collected in glass or polymer bottles. Glass vessels are frequently silanized in order to minimize losses due to adsorption on the walls. Brown glass is used to stop biological and chemical processes which can occur under the influence of light. Teflon and polyethylene are frequently used. During sampling the vessels should be filled to the top to exclude air and minimize head space losses.

Isolation and/or Preconcentration

Because direct analysis of sulfur compounds in water matrices is often impossible, various preconcentration or isolation procedures are applied before the analysis proper. Solvent extraction and static and dynamic headspace techniques are most popular.

Liquid extraction Solvent extraction is not as frequently applied as formerly because this technique has several disadvantages, i.e., handling toxic solvents, the trapped substances become diluted, automation is difficult and the procedures are time consuming. The most popular solvents for the VSCs are diethyl ether, hexane or mixtures of these solvents.

Static gas extraction methods Headspace-gas chromatography (HS-GC) analysis can be applied

successfully for the analysis of VSCs in different liquid matrices. It can be also applied in physical chemistry studies of these compounds, being a valuable tool for acquiring data on gas–solid and gas–liquid systems. For example, it was used for the determination of distribution coefficients, K , of selected organosulfur compounds in air–water systems as well as their temperature, ionic strength and concentration dependencies.

Generally, the detection limit of the static headspace technique is 10 to 100 times poorer than that of the dynamic technique, i.e., purge and trap (PT).

Dynamic gas extraction methods Purge and trap assemblies can be used for isolation and preconcentration of volatile sulfur species in water samples. The extraction efficiency varies with the gas considered and the extraction facilities employed such as the dimensions of the purge vessel, bubble size distribution, sample volume and temperature, purge gas flow rate and sparge time. All these parameters should be carefully considered before applying the technique for a particular purpose.

Due to the low detection limits which can be obtained with the PT technique, it is extensively used to determine VSCs in water. Several PT procedures have been developed especially for the most important natural sulfur compound – dimethyl sulfide (DMS) – a climatically active trace gas.

Recently, there has been an interest in dimethyl sulfoxide (DMSO) determination. DMSO is also an environmentally significant compound because of its potential role in the biogeochemical cycle of DMS. Direct injection and separation of aqueous DMSO offers a simple and fast application, but exhibits limited sensitivity due to limitation on injection volumes. More frequently, DMSO reduction and subsequent analysis of the evolved DMS by purge-and-trap preconcentration has been used.

The P&T technique can also be applied for the determination of sulfur species in sediments.

Sulfur Compounds of Fossil Fuel-Origin

Trace level sulfur speciation and detection in crude oil and in different petroleum products is traditionally difficult due to the complex hydrocarbon matrix. Additionally, the fact that sulfur compounds are polar and the hydrocarbons matrices are non-polar favours the loss of sulfur compounds to active sites in analytical instruments and sample vessels. The development of sulfur-specific detectors for gas chromatography has added impetus to use of this technique for the analysis of petroleum fractions. For

example, selectivity of the sulfur chemiluminescence detector (SCD) allows the determination of sub-ppm level of sulfur compounds in the presence of percent levels of co-eluting hydrocarbons.

The usual approach for characterization of the very complex nature of different individual sulfur compounds in a crude oil is to fractionate the oil into narrow boiling range cuts (prefractionation) and to analyse each fraction, which simplifies the analysis. Sample preparation/cleanup is needed, especially for analysis of high boiling fractions (coal-derived liquids, shale oil), before GC, Solid phase extraction (SPE), using various cartridges with different solvent mixtures, followed by normal-phase liquid chromatography has been applied for separation of polycyclic aromatic sulfur heterocyclic compounds (PASHs) from polycyclic aromatic hydrocarbons (PAHs). PASHs can be found not only in fossil fuels, but also in sediments, mussels, fish and airborne particulate matter. The separation and determination of individual alkyl-substituted PASHs isomers in environmental matrices is difficult because of the isomeric structures of these species due to asymmetry imposed by the sulfur atom. Relatively good resolution of many PASHs isomers has been obtained on a smectic liquid crystal column (**Figure 1**).

In research and in everyday practice, one frequently encounters situations where not only the concentrations of both sulfur and non-sulfur compounds but also both percentage levels and low concentrations (ppm and ppb levels) of sulfur species have to be determined. In such cases two parallel detectors can be used. For example, coupling of sulfur chemiluminescence (SCD) and thermal conductivity detectors (TCD) enables the determination of concentration of both sulfur-containing (from percentage to ppb levels) and other gaseous compounds through simultaneous sampling, separation, and detection. Also simultaneous SCD and FID detection can be useful in many cases.

The sulfur-selective detectors, mainly SCD and atomic emission detector (AED), can be interfaced to simulated distillation (SimDis) systems to measure the boiling point range distribution of heteroatoms (S and N) in various petroleum fractions. Such an approach is applied for process control, quality assurance and product specification purposes. Very good sulfur SimDis chromatograms have been obtained considering the fact that typical sulfur levels in refinery streams are several orders of magnitude lower than the hydrocarbon levels.

The sulfur-selective detectors have been used for oil spill identification by finger-printing of various crude oils. The specific identification of different dibenzothiophenes by GC–high resolution MS has

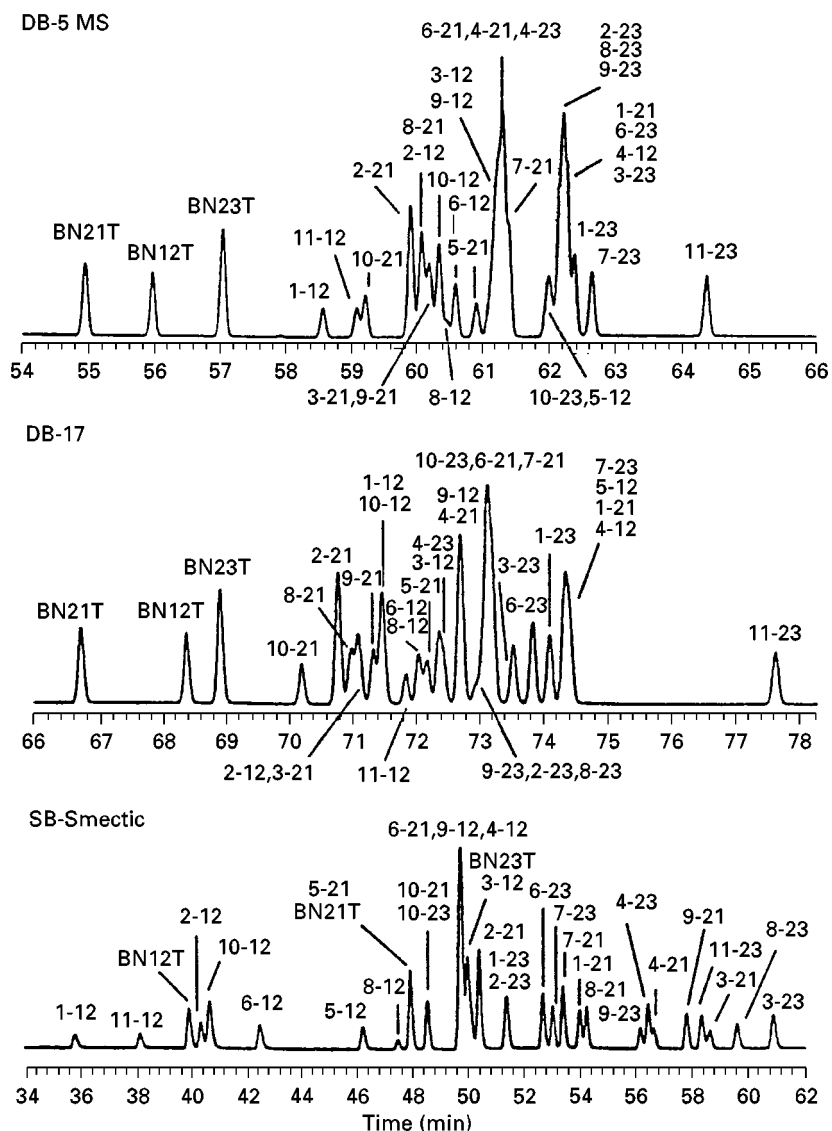

Figure 1 GC-MS separation of 3 benzo[*b*]naphthothiophene (BNT) (m/z 234) isomers and 30 methylbenzo[*b*]naphthothiophene (MeBNT) isomers (m/z 248) on different stationary phases: DB-5MS, DB-17 and SB-Smectic. BN12T = benzo[*b*]naphtho[1,2-*d*]thiophene, BN21T = benzo[*b*]naphtho[2,1-*d*]thiophene, and BN23T = benzo[*b*]naphtho[2,3-*d*]thiophene. Numbers identify the specific methylbenzo[*b*]naphthothiophene isomers, e.g., 1-12 = 1-methylbenzo[*b*]naphtho[1,2-*d*]thiophene, 8-21 = 8-methylbenzo[*b*]naphtho[2,1-*d*]thiophene, 11-23 = 11-methylbenzo[*b*]naphtho[2,3-*d*]thiophene, etc.

permitted differentiation of very similar crude oils, even from the same field.

The ability to speciate the sulfur compounds is an advantage of GC method over elemental analysis, but total sulfur can also be determined by GC by summation of all the sulfur-containing peaks.

Sulfur Compounds in Beverages and Foodstuffs

Volatile sulfur compounds have been detected in wine, beer (Figure 2), dairy products, coffee, fish, garlic and tobacco smoke. In food chemistry

these compounds contribute significantly to odour and flavour because they often possess characteristic smells and sensory thresholds (ca. $1 \mu\text{g kg}^{-1}$ for DMS).

For isolation of sulfur compounds from different food matrices, headspace sampling (HS) is the best method. For example, HS-GC has been used for the determination of VSCs in water-alcohol solutions and brandies. It was found that headspace concentrations of sulfur, H_2S , MeSH , EtSH , DMS, CS_2 , DES, thiophene, DMDS and DEDS increased with increasing ratio between the gas and liquid phase volumes and was proportional to the temperature. However, it

Figure 2 GC-SCD chromatograms of (A) a beer with a sulfury character and (B) a non-sulfury beer. GC conditions: column: DB-5, 30 m, 0.53 mm I.D., 1.5 μ m film thickness; injector temperature: 150°C; column temperature programme: 20–50°C at 5°C min⁻¹, 50–180°C at 8°C min⁻¹, 10 : 1 split injection. Peaks: (1) methanethiol; (2) dimethyl sulfide; (3) ethylene sulfide; (4) diethyl disulfide; (5) dimethyl disulfide; (6) isopropyl sulfide (internal standard) and (7) dimethyl trisulfide.

diminished with increasing ethanol content and was insensitive to the liquid phase salt concentration. HS sampling has also provided qualitative and quantitative data of sulfur species in dairy products.

Storage Stability of Samples

In order to avoid losses or possible transformations of sulfur compounds, samples should be analysed as soon as possible. Keeping the samples at sub-ambient temperature can improve the stability of sulfur compounds. Sulfur concentrations in an air sample

collected cryogenically and stored in a freezer were found not to change over a 2 week period. A Tenax trap containing VSCs collected from air was stored for at least 1 week at 196°C in liquid nitrogen without any loss of sulfur compounds.

For sulfur gases the most convenient method of storage seems to be in Tedlar bags. The concentrations of the five sulfur gases (COS, CS₂, MeSH and EtSH) in such bags were stable for two weeks even at the ppb concentration. Tedlar bags are not suitable for SO₂ and H₂S. In these cases, SO₂ concentration decreased from 22 ppb to less than 1 ppb in 2 h and

H₂S lost half of its original concentration of 70 ppb in about 10 days. The stability of sulfur gases in glass sampling bulbs is influenced by the gas matrix (nitrogen and air) and moisture. Reduced sulfur gases collected in glass bulbs can remain in the bulbs for approximately 24 h without major changes in gas concentrations if the sample is dry and does not contain oxygen (concentration decreased less than 5%) but dried air samples should be analysed within 3 h. Glass bulbs are not useful for collecting sulfur gases if the sample in the bulbs contains moisture (significant decrease in H₂S and MeSH concentrations was observed).

The stability of freshwater samples is strongly affected by the temperature at which it is stored. For example, it was reported that the stability of DMS in freshwater is shorter than the 48 h found in seawater samples.

Because the presence of reduced sulfur compounds in seawater is closely related to biological activity, the stability of samples may depend on the depth of sampling. When a sample was taken from the Baltic Sea at 4 m depth and was stored at 5°C in the dark, the concentration of DMS first rose dramatically after 4 days (nearly 10 times) and later decreased. Concentration of sample taken from 50 m depth did not change over a 2 week period. Samples can most probably be stored longer if the cold trap is maintained in liquid nitrogen.

To suppress microbial activity, compounds such as phenols, mercuric chloride, sodium azide and HCl can be added to water samples.

When immediate analysis is not possible, refrigeration of sample for analysis of sulfur compounds in aqueous solutions is recommended as the best way to maintain sample integrity at least for periods up to 48 h.

Separation Systems

Column packing for chromatographic determination should be chosen not only with respect to the complete separation of a given mixture but should also be selected with respect to minimize losses due to adsorption and catalytic reactions and rearrangements. These are particularly important when packed metal and glass column are used.

The most common material used for packed columns in the analysis of VSCs is Teflon. Supelpack S (specially treated Porapak QS), different Chromosorbs, Porapak Q, N or QS, Triton X 305, Chromosil 310 or 330 (specially treated silica gel), Carbopack B or BHT 100 and 3% polyphenyl ether and 1% phosphoric acid on Chromosorb T have all been reported for VSCs analysis.

Good separation of many gaseous sulfur compounds can be obtained on Chromosil 310 and 330 and Supelpack (Figure 3). The latter can resolve the

Figure 3 Trace light sulfur gases and C1–C3 mercaptans. (From Supelco Bulletin 722, reprinted with permission of Supelco, Bellefonte, PA 16823, USA.)

large peak of CO_2 (evolved from acidified seawater) from the much smaller and neighbouring H_2S and COS peaks.

Development of fused silica capillary columns has provided more inert surfaces for trace sulfur analysis. As with most analysis, no single capillary column can assure the combination of sample capacity, good resolution and reasonable analysis time for the wide range of sulfur species in different sample matrices. The analysis of VSCs has been achieved with methyl silicone phases like BD1 or Rtx1 with thick films (4–5 μm). Generally, columns with thicker films provide increased separation of volatile sulfur compounds and are better suited for analysis of low level volatile sulfur compounds in gases (Figure 4). On such non-polar columns retention times are governed primarily by boiling points and the retention sequence can be predicted from boiling-point data.

Thick films separate most VSCs in programmed temperature analysis with an initial temperature of 40–50°C. For the separation of H_2S , COS and SO_2 sub-ambient column temperatures must be used (Figure 5).

Recently, porous layer open tubular (PLOT) columns have become commercially available. The usefulness of such columns has been demonstrated for analysis of sulfur compounds such as COS, H_2S and DMS.

Smectic liquid crystalline columns may offer unique selectivity for isomeric polyaromatic sulfur compound (PASHs) mixtures that are not possible with other columns. Unfortunately, extensive use of the SB-smectic column at the upper temperature limit (250°C isothermal, 270°C during temperature programmed) can reduce the useful lifetime and column selectivity often changes dramatically with use.

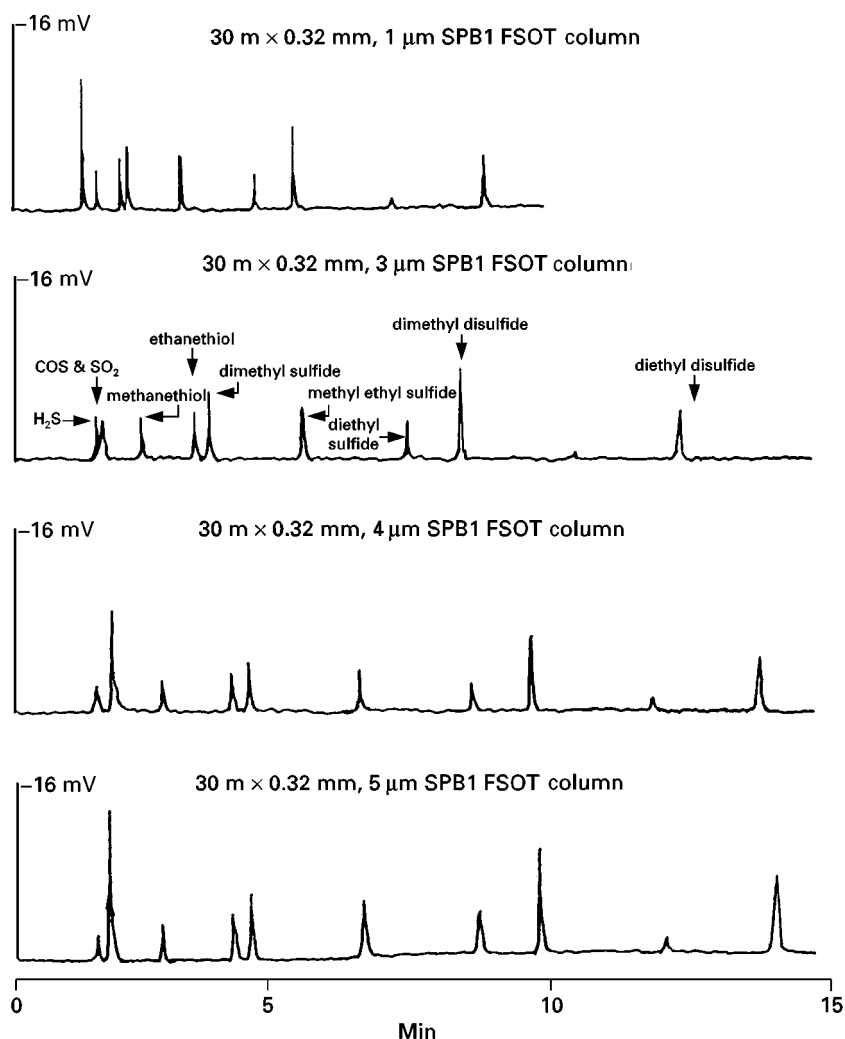

Figure 4 Effect of stationary film thickness on the separation of sulfur-containing compounds. Sample: gas phase standard of 10 component mixture of sulfur compounds: 1 mL split injection (split ratio 10 : 1), SCD, temperature programme 1 min at 35°C, 35–200°C at 10 min. Reproduced with permission from Hutte (1990).

Figure 5 Sub-ambient column temperature separation of sulfur gas standard: GC conditions: 1 mL split injection (split ratio 10 : 1), injection port at 250°C, FID temperature 300°C. Column temperature programme: 2 min at -30°C, -30-200°C at 20° min⁻¹. Detector conditions: SCD integration time 0.03 s. Reproduced with permission from Hutte (1990).

Detection Systems

The value of GC for sulfur compounds analysis is found in the availability of selective and sensitive detectors. These detectors are especially useful because matrices requiring sulfur analysis are often very complex. Such detectors can reduce the analysis time by eliminating laborious and time-consuming procedures of sample preparation, which can also often cause contamination or loss of analytes. Selective detectors have found extensive application in the determination of sulfur compounds in various matrices because of these reasons.

Table 1 lists the basic characteristics of the most frequently used sulfur-selective detectors.

The flame photometric detector (FPD) is still the most widely used sulfur selective detector. The FPD exhibits a non-linear (exponential) response to sulfur compounds and response factors may be compound-dependent but it is relatively inexpensive, robust and adequate for many applications. The major advantage of the FPD is its application to gases and fuels. However, major co-eluting hydrocarbons pres-

ent in liquid fuels have a quenching effect on the sulfur response. Also the injection of aqueous samples directly into a GC-FPD system is not recommended because the injected water can extinguish the detector flame and non-volatile material contained in the sample can contaminate the injection port and column. An increase of the detector temperature prevents the flame from being extinguished but working at temperatures higher than 250°C may produce a poor baseline. An improved FPD called a pulsed flame photometer detector (PFPD) employs a pulsed flame and time-resolved emission detection with gated electronics. The improvements include one to two orders of magnitude sensitivity enhancement, about an order of magnitude of increased selectivity and reduced quenching effects.

A more recent alternative to the FPD is the sulfur chemiluminescence detector (SCD). Recent applications of this detector have shown that it gives good performance in terms of detectability, selectivity, linearity and a nearly equimolar response to sulfur. It does not suffer significantly from quenching or interferences. The combination of fused silica capillary

Table 1 Basic characteristics of gas chromatographic sulfur-sensitive detectors

<i>Detector</i>	<i>Detection limit [gS/s]</i>	<i>Selectivity [S/C]</i>	<i>Linear concentration range (decades)</i>	<i>Ease of operation</i>	<i>General characteristics</i>
FPD	10^{-11}	10^{-3} – 10^5	3 ^a	Moderate	Exponential and compound-dependent response, susceptible to flame-out and quenching effects
PFPD*	10^{-13}	10^6	3 ^a	Moderate	Less quenching than for the regular FPD
ECD	Variable up to 10^{-15}	Variable	4	Simple	Strongly compounds-dependent response, very high sensitivity to SF ₆ itself or post-column converted sulfur compounds
SCD** (flame version)	10^{-12}	$> 10^6$	4–5	Moderate	Linear and nearly equimolar response, non-susceptible to quenching or interferences, very convenient for petroleum applications
SCD (non-flame version)	10^{-13}	$> 10^7$	4–5	Simple	
AED***	10^{-12}	10^4	3–4	Difficult	Small susceptibility to quenching or interferences, possibility of elemental composition confirmation
HECD ⁺	10^{-11}	10^4 – 10^6	3–5	Complicated	Possible interferences of other organic compounds
PID ⁺⁺	10^{-12}	Poor	6	Moderate	Many factors influence the detector response
MS	10^{-11}	Specific	5	Complicated	Convenient for identification of complex mixture, new membrane techniques assure lower detection limit
FT-IR	10^{-12}	Specific	4	Complicated	Applied only for highly complex mixture. Strongly compound-dependent

⁺ Hall electrolytic conductivity detector.⁺⁺ Photoionization detector.

columns and the SCD provides a powerful tool for the measurements of trace levels of sulfur containing compounds in complex matrices (Figure 6). The performance of the SCD can be improved by changing the means of sulfur-chemiluminescent-species production from a hydrogen flame (commonly referred to as a flame SCD) to a closed hydrogen/air burner (a flameless SCD). The flameless SCD is typically an order of magnitude more sensitive than the flame version. An extremely low detection limit of 25 fgS/s has been reported but most authors have observed a limit between 0.1 and 1 pgS/s.

The atomic emission detector (AED) has a good combination of specificity and sensitivity for the analysis of volatile sulfur-containing compounds. The AED is better than the FPD because it does not exhibit as many problems with interferences, quenching, and compound-dependent responses. The AED can be used to confirm the elemental composition of

a compound by its ability to monitor several atomic lines simultaneously. The response of the AED to sulfur at 180.7 nm is reported to have linear range of 2×10^4 , and sensitivity of 1.7 pgS/s and a selectivity over carbon of 1.5×10^3 .

The electrolytic conductivity detector (HECD or Hall detector) has found limited applications in analysis of VSCs probably because it requires regular attention. The electrolyte must be kept extremely clean and sulfur specificity is limited by high concentrations of co-trapped carbon dioxide. Despite these problems, the HECD performs well in the sulfur detection mode. The detector response is linear up to 50 ng sulfur, selectivity of sulfur to carbon is typically better than 10^4 , and the limit of detection is 1 pgS/s.

The electron-capture detector (ECD) can also be used for determination of a variety of sulfur containing compounds, e.g., SO₂, H₂S, thiols and organic

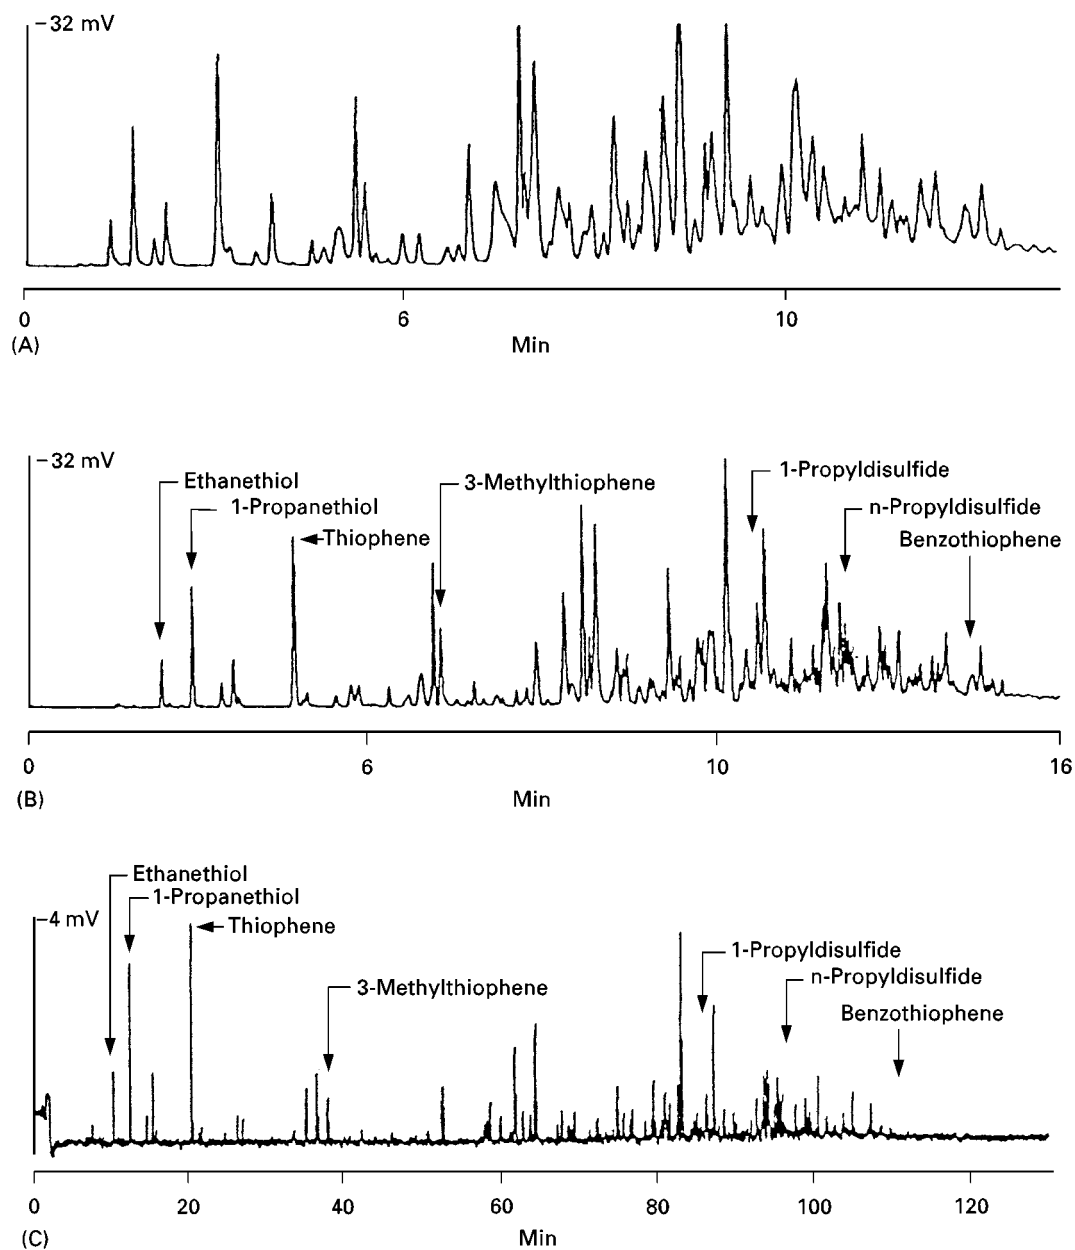

Figure 6 Comparison of column resolution for the analysis of sulfur components of raw naphtha feedstock (SCD). Capillary columns: A: 15 m \times 0.53 mm i.d. DB-1 (1.5 μ m film thickness); B: 30 m \times 0.32 mm i.d. SPB-1 (1 μ m film thickness); C: 100 m \times 0.25 mm i.d. SPB-1 (0.5 μ m film thickness). GC conditions: 1 μ L direct injection for column A, 1 μ L split injection for column B (split ratio 10 : 1) and column C (split ratio 100 : 1). Injection port temperature 250°C. Column temperature programme: column A: 1 min at 35°C 35–200°C at 8°C min⁻¹; column B: 1 min at 35°C, 35–200°C at 10°C min⁻¹; column C: 13 min at 35°C, 35–45°C at 10°C min⁻¹, 15 min at 45°C, 45–60°C at 1°C min⁻¹, 60–300°C at 2°C min⁻¹. Reproduced with permission from Hutte (1990).

mono- and di- and trisulfides. Although the ECD is only moderately sensitive to SO₂ and H₂S, both are detected in the concentration range 0.1–1 μ g g⁻¹ in a 1 mL air sample. For COS, CS₂, MeSH, H₂S and DMDS the detector displays a sensitivity comparable to the FPD but is much less sensitive towards DMS and thiophene. SF₆ can be detected at extremely low levels with minimum detectable peaks lower than 0.2 fmol. The inertness and extremely low detectabil-

ity of SF₆ has led to the development of a method in which the original sulfur compounds are fluorinated and then detected as SF₆.

The application of GC-MS systems is becoming more popular in the analysis of various sulfur compounds. Determination of sulfur compounds in underground reservoirs of natural gas and town gas (RSH, RSR and RSSR type compounds) by GC-MS has been carried out using the ion CH₂ = S⁺H

Table 2 Representative examples of sulfur gas determination by gas chromatography

Matrix	Analysed compounds	Sample preparation	Column		Dimension	Temperature conditions	Detector	Detection limit
			Material	Packing				
Atmospheric sulfur gases	COS, MeSH, CS ₂ , DMS, SF ₆	Chemisorption on gold wool + cryotrapping or only direct cryotrapping	Fused silica	BP-1	30 m × 0.32 mm × 1 µm	Isothermally, 35°C	AED	0.1 nmol m ⁻³
Air from a petroleum plant	H ₂ S, C ₁ –C ₇ thiols, DMS	Trapping on Tenax TA, placed in PTV injector, cryotrapping on column	Fused silica	GS-Q	30 m × 0.53 mm	1 min at 100°C, 100–240°C at 8°C min ⁻¹ , 30 min at 240°C	FPD	pgS
Gases from sweetening process	H ₂ S, COS, CS ₂ , thiophene, MeSH, (ppm level) in CH ₄ , CO ₂ , C ₂ H ₄ (% level)	Direct injection	Fused silica	CP-Sil 5CB	50 m × 0.32 mm × 0.5 µm	3 min at 75°C; 75–120°C at 20°C min ⁻¹	SCD TCD	ppb level
Gases from workplace environment	DMS, DES	Trapping on Tenax TA, cryofocusing (–150°C)	Stainless steel	Porapak Q	4 m × 3.2 mm o.d.	10 min at 120°C		
			Fused silica	DB-1	15 m × 0.52 mm × 1.5 µm	2 min at 60°C; 60–100°C at 10°C min ⁻¹ , 1 min at 100°C; 100–250°C at 30°C min ⁻¹	FPD + FID	µg m ⁻³
Atmospheric gas	DMS, DMDS in presence of volatile organic compounds	Cryogenic trapping on Tenax (Peltier effect)	Fused silica	Paraplot Q	10 m × 0.32 mm	7 min at 55°C; 55–216°C at 12°C min ⁻¹	MS	ppt level
Tropospheric airborne gases	COS, H ₂ S, CS ₂ , DMS	Trapping in Teflon trap (liquid argon) After separation fluorination to SF ₆					FPD MS ECD	ppt level
Atmospheric sulfur gases	H ₂ S, COS, SO ₂ , DMS MeSH, CS ₂ , DMDS EtSH, iPr SH	Cryogenic trapping in Teflon trap or in FSOT retention gap	Fused silica	DB-1/DB-Wax	30 m × 0.53 mm × 5 µm/ 3 m × 0.53 mm × 1 µm	1.2 min at 30°C; 30–140°C at 30°C min ⁻¹ , 2 min at 30°C; 30–140°C at 15°C min ⁻¹	FPD MS	50 pgS 5 pgS
Antarctic atmosphere	SF ₆	Sorption on Porapak Q (–77°C)	Stainless steel	Molecular sieve 5A	30 cm pre-column + 3 m	Isothermally, 65°C (back flushed when SF ₆ reaches main column)	ECD	ppt level

Table 3 Representative examples of sulfur compound determinations in aqueous matrices by gas chromatography

Matrix	Analysed compounds	Sample preparation	Column			Temperature conditions	Detector	Detection limit
			Material	Packing	Dimension			
Antarctic marine waters	H ₂ S, COS, SO ₂ , MeSH, DMS	Purging, preconcentration on Tenax TA (ambient temperature), thermal desorption	Teflon	Carbopack B/1.5% XE 60/1% H ₃ PO ₄	3 m × 0.25 mm	40–140°C–temperature programming	FPD	6–160 ng L ⁻¹
Atlantic surface water	DMS, DMDS, CS ₂ , dimethyl selenide, dimethyl iodide	Purging, trapping in cold trap	Fused silica	SE-54	50 m × 0.32 mm × 5 µm	3 min at 70°C, 70–180°C at 3°C min ⁻¹	AED or ECD	0.5–0.8 ppm
Aqueous matrices (distilled water, tap water, kraft mill condensate)	H ₂ S, MeSH, DMS, DMDS	Filtration with glass fibre filters, direct injection split mode (10 : 1)	Fused silica	DB Wax	30 m × 0.53 mm × 1 µm	5 min at 40°C; 40–160°C at 30°C min ⁻¹ , 3 min at 160°C, 160–200°C at 40°C min ⁻¹	FPD	0.3 mg L ⁻¹
Heavily polluted water	H ₂ S, COS, MeSH, DMS, CS ₂ , DMDS	Purging, cryogenic trapping (–80°C)	Teflon	Carbopack BHT-100	1.4 m × 3 cm	1 min at 5°C; 5–50°C at 30°C min ⁻¹ , 2 min at 50°C; 50–100°C at 30°C min ⁻¹ , 7 min at 100°C	FPD	ng S
Water samples, sediments	H ₂ S, COS, MeSH, DMS, CS ₂ , DMDS	Purging, cryocondensation secondary cryofocusing	Teflon	Carbopack BHT-100	1.4 m × 3.2 cm	–5–100°C at 30°C min ⁻¹ , 8 min at 100°C	FPD	pg S
Surface and potable water, industrial effluents, sediments	21 organosulfur compounds (thiophenes, sulfides, sulfones, benzothiazole)	Purging, trapping on Tenax, extraction with hexane or methylene chloride	Fused silica	DB-5	25 m × 0.25 mm × 0.33 µm	4 min at –50°C, –50–200°C at 16°C min ⁻¹ , 8 min at 200°C; 200–220°C at 16°C min ⁻¹	MS	ppb level
Anoxic-lake water	H ₂ S, COS, MeSH, CS ₂ , EtSH, DMS	Purging, cryotrapping on Tenax TA (solid CO ₂), heating with hot air (200°C)	Glass	UCON 50 HB 5100	25 m and 50 m	0°C–45°C at 3°C min ⁻¹	FPD, MS	ng L ⁻¹

with m/z 47. The ion with m/z 45 is more intense in some sulfur compounds, but is often found in oxygen compounds ($C_2^+H_4OH$) as well. Twenty-one organosulfur compounds (DMS and DMDS among others) were detected in the approximate concentration range 0.1 to 2000 ppb in water, industrial effluent, sediment and fish samples using an automated GC-MS system. A GC-MS method for DMS and SO_2 determination in air in real time at the sub parts per trillion level with a high pressure selected-ion chemical ionization flow reactor has been developed. The use of isotope dilution GC-MS with perdeuterated DMS for DMS determination in sea water gives better than 2% precision. By using the ratio of the MS response at m/z 62 and m/z 68, compensation can be made for instrumental drift as well any losses in sampling ambient air. Another significant advantage is the ability to determine DMS concentration by stripping only a small fraction of DMS from solution, resulting in artefact-free DMS concentration. In addition, larger volumes of water can be sampled by eliminating the need for long sampling periods required to remove DMS quantitatively from solution. Highly sensitive and specific continuous measurement of DMS in air, using triple quadrupole mass spectrometry with atmospheric pressure chemical ionization, has been demonstrated. Detection limits in continuous direct monitoring were determined for DMS (24 pptv), H_2S (1 ppbv), for MeSH, COS and CS_2 (about 10 ppbv).

Calibration

The preparation of reliable standard mixtures is an important step in analysis. The simplest way to calibrate a GC system for gas analysis is by injecting a suitable volume of a standard gas. Low concentration standards, usually needed in trace analysis, can be obtained by applying the exponential dilution flask technique or with permeation tubes. To minimize non-linear response problems (as for flame photometric detector) the calibration curves should cover the anticipated concentration range. For calibration, the gases from diffusion tubes are diluted with an inert gas and frequently led through a glass loop injected onto the column with appropriate valves. A new concept for the generation of standard mixture of thiols, based on thermal decomposition of a substance chemically bonded to the surface of silica gel, has been developed. The method enables preparation of a standard mixture containing volatile, malodorous, unstable and toxic compounds. For example, standard mixture of MeSH and PrSH have been generated by heating silica gel with anchored dithiocarbamate groups.

In analysis of liquids, primary standards are usually prepared in an appropriate solvent which should not interfere with the determined compounds. All standard solutions should be stored in vials with headspace volume as small as possible and kept at low temperature ($\leq 4^\circ C$).

Examples of Applications

Due to the diversity of sulfur compounds and various matrices in which they can be present, the chromatographer is faced with a difficult task when separation, identification and quantification of specific sulfur species are desired. The approach needed for the analysis of these compounds depends on several factors. In choosing the appropriate procedure, the analyst should consider the form of sulfur compounds to be determined, their levels of concentrations, the physical state and the complexity of the matrix. Tables 2–5 present representative examples of sulfur compounds determination in various matrices using gas chromatography. The examples include sample preparation techniques, columns with chromatographic conditions, and detectors.

Conclusions

Gas chromatography, especially high resolution gas chromatography, perhaps more than other methods, fulfils the requirements needed for the analysis and structure elucidation of multicomponent environmental mixtures in which different sulfur species can be present in nanogram or picogram amounts. It should be noted that, besides selective high resolution columns and sensitive sulfur-specific detectors, most qualitative and quantitative determination of sulfur-containing compounds requires efficient sample enrichment techniques and quantitative desorption from traps. The applied procedure should also minimize adsorption losses of the sulfur compounds in the whole analytical system and reduce possible rearrangements of sulfur analytes. Significant progress is still being made in all steps of sulfur analysis in various environmental matrices but such procedures are not still routinely applied in many laboratories. Future developments should be focused on procedures that can be used during long research expeditions, directly aboard ships, or in situ for real-time measurements.

Introduction

Supercritical crystallization processes use the special properties of supercritical fluids that make these fluids particularly suitable as solvents or antisolvents. In both cases, an expansion of a solution is used to create supersaturation, which is the driving force for nucleation and growth of the solute.

A supercritical fluid (SCF) is a fluid above its critical temperature and pressure. It is characterized by physical properties (such as viscosity and diffusivity) that can be continuously varied between those of liquids and gases. The liquid-like density of a SCF is associated with its ability to dissolve solutes, and hence its solvent power. Since this density can be changed significantly by changing the pressure and temperature in the critical region, the solvent properties of a supercritical fluid can be tailored for specific applications. **Figure 1** shows the relationship between pressure and density of carbon dioxide. The region above the critical pressure and temperature

(7.38 MPa, 302.3 K) is commonly referred to as the supercritical region of carbon dioxide. It is important to note that the largest changes in the fluid density with changes in temperature and/or pressure in the single-phase region occur near the critical point. Therefore, large changes of solvent power can be achieved with small changes in pressure or temperature in the critical region. It should be added here that a supercritical crystallization process involves mixtures of solute and solvent; however, these mixtures are generally dilute so that their critical points are close to the critical point of the solvent. The behaviour depicted in **Figure 1** may therefore be considered to be representative of the behaviour of dilute mixtures of constant composition.

If a supercritical fluid loaded with solute is expanded, then the resulting change in density may lead to precipitation of the solute. If these changes in density are made to occur rapidly, then the process is known as the rapid expansion of supercritical solutions, or RESS. Very high supersaturations may be achieved in RESS processes over a very short period of time. This generally favours the deposition of small crystals and narrow size distributions. Also, the crys-

Figure 1 Pressure-density behaviour of CO_2, 330 K; —, 310 K; ----, phase boundary.

tals are generally free of solvent inclusions because the solvent is likely to be in the gaseous state at the end of the expansion.

Introduction of a supercritical fluid into an organic solvent can also result in expansion of the liquid phase, and hence, in large changes in density. If a solution containing a desired solute is expanded sufficiently by the supercritical fluid, then the liquid phase will no longer be a good solvent for the solute and nucleation will occur. In this case, the supercritical fluid acts as an antisolvent, and the crystallization process is known as the supercritical antisolvent (SAS) process, or by a variety of other names that are discussed below. Changes in the pressure, temperature, or rate of supercritical fluid addition provide an opportunity for tailoring the SAS crystallization process for specific applications.

Crystallization by the Rapid Expansion of a Supercritical Solution (RESS)

The rapid expansion of a supercritical solution (RESS) by decompression can lead to very large changes in density and, hence, in the solubility of a solute in the supercritical solvent. This can result in very high supersaturation when supercritical solutions are depressurized, leading to the formation of a large number of nuclei. A typical RESS apparatus is shown in Figure 2. Solvent is pressurized in a pump until a pressure above its critical pressure is attained. The supercritical state is achieved by passing the pressurized solvent through a heat exchanger maintained at a temperature above the critical temperature of the solvent in a constant-temperature bath. The super-

critical fluid is then passed through a bed of solute where it becomes saturated with the solute. The loaded solution is then heated to a designed pre-expansion temperature, and finally expanded quickly through an expansion device, such as a nozzle or a capillary, into a collection vessel. The expansion device is generally heated to prevent resublimation or solvent condensation. The collection vessel is maintained at a constant temperature and pressure or vacuum, and the products are collected on a suitable substrate placed in the path of the expansion jet. The pressure in the collection vessel is ambient, but may sometimes be higher in order to control the particle size; or it may be below atmospheric to prevent condensation of any solvent that is a liquid at ambient conditions. Variations of this equipment are possible, particularly if the solvent is to be recycled. Also, a dual RESS or DURESS process has been proposed whereby two RESS expansions are carried out in a concentric expansion device and yield, for example, a solid solute coated with a polymer.

The RESS process is applicable to any material that can be dissolved in a supercritical solvent and is particularly useful for materials of low volatility. A few examples of crystallized materials using the RESS process are shown in Table 1. Scanning electron microscopy (SEM) micrographs of crystals obtained by RESS processes are shown in Figure 3. RESS expansions result in essentially homogeneous nucleation of the solute. The morphology of the product is determined by a number of factors, including the solute and its concentration, the device used for the expansion, the pre-expansion temperature, the flow rate, and the pressure drop on expansion. High concentrations of solute tend to produce powders, whereas low concentrations generally produce thin layers or films. The particle size has been found to increase with solute concentration prior to expansion. Also, processing conditions may be chosen such that the solvent is a gas at exit conditions and can be easily separated from the deposited solute. If conditions are chosen so that a two-phase mixture is

formed during the expansion, solid may condense to yield a thin solid film.

There is a possibility of fibre formation from supercritical solutions when an organic polymer is the solute. The polymer may form either a liquid or solid after decompression, depending on the polymer melting temperature relative to the post-expansion temperature. Fibres are generally formed when the expansion is carried out in a capillary nozzle and the post-expansion temperature is close to the melting temperature of the polymer so that the polymer deposits as a liquid on the nozzle walls. RESS expansion of polymers yields powders when the temperature is not close to the melting temperature of the polymer. The extremely short times of product formation in

the expansion of supercritical solutions also makes it possible to produce multicomponent mixtures of powders with uniform distribution of the components. Such powders have tremendous commercial potential in the ceramic industry.

The pressure, temperature, and supersaturation profiles in and outside the expansion device determine the size of the crystals produced in the RESS process and the crystal size distribution. The pressure and temperature profiles in the expansion device can be modelled by solving the mass, energy, and momentum conservation equations for the adiabatic expansion of the supercritical fluid. Typical profiles for a capillary nozzle are shown in **Figure 4**. The free-jet expansion after the fluid exits

Figure 3 SEM micrographs of *n*-octacosane crystals obtained in RESS expansion of a CO₂ solution.

the device can also be modelled and is shown schematically in **Figure 5**. Calculations have shown that a Mach disc is formed a few nozzle diameters downstream from the nozzle exit and that the pressure and temperature are very low in the region between the exit and the Mach disc. High supersaturations may therefore be obtained before, in, or after the fluid exits the nozzle and the exact profile must be known

if control of the crystal size and crystal size distribution is desired.

Crystallization by the Addition of a Supercritical Antisolvent (SAS)

In the supercritical antisolvent (SAS) process, a pressurized fluid is used as an antisolvent for precipitating a solid that is dissolved in a liquid solvent. The supersaturation of the solid is created by the volumetric expansion of the liquid solution. After crystallization of the solute, it is possible to remove the antisolvent completely by pressure reduction. Control of the particle size distribution is also possible by manipulation of the process variables.

Many organic solvents show at least partial miscibility with gases and supercritical fluids at moderate to high pressures. Introduction of the SCF antisolvent into such organic solvents will result in dissolution of the antisolvent and an expansion of the liquid phase. This expansion can be quite significant, as shown for ethyl acetate–carbon dioxide mixtures in **Figure 6**. In

Figure 6 Volumetric expansion of an ethyl acetate with CO₂. —, 25°C; ----, 30°C; ···, 40°C.

Figure 7 Experimental apparatus for a batch SAS process.

this figure, $\Delta V(\%)$ is defined as follows:

$$\Delta V(\%) = 100\{V(p, T) - V_0\}/V_0 \quad [1]$$

where $V(p, T)$ is the volume of the liquid phase when loaded with antisolvent, and V_0 is the volume of the pure liquid phase at atmospheric conditions. This expansion is large near the critical temperature of the antisolvent.

The following requirements must be satisfied for a successful SAS process: the solute must be soluble in the organic solvent at ambient temperatures and insoluble (or sparingly soluble) in the SCF antisolvent. The organic solvent must be at least partially miscible with the SCF antisolvent as described above. Many organic solids satisfy these requirements, although this is not true of inorganic compounds. Inorganic compounds are generally soluble in water or acids such as sulfuric acid, but these solvents do not expand appreciably when contacted with simple gases such as

CO₂ or light hydrocarbons. However, many cobalt, nickel iron and chromium salts are soluble in acetone, cyclohexane or *N*-methylpyrrolidone, and these solvents have been used to develop SAS recrystallization processes.

The SAS process may involve antisolvent injection into a liquid phase (gas injection) or liquid solution injection into a SCF antisolvent (liquid injection) operation. Both these processes can be operated continuously or in batch mode.

A typical experimental apparatus for batch operations is shown in **Figure 7**. In the case of gas injection, a vessel is loaded with a known quantity of liquid solution containing the dissolved solute, and then the SCF antisolvent is added to the solution from the top or bottom of the vessel. This causes the liquid phase to expand and the solute to precipitate. The rate of antisolvent addition is an important parameter for the control of morphology and size of the solid particles obtained in this process. Rapid addition of the antisolvent generally leads to smaller and more uniform particles. Slower addition of the SCF can result in a range of particle sizes. The morphology of the particles can also be controlled by the rate of antisolvent addition, and by the organic solvent used to dissolve the solute. Examples of particles precipitated in gas injection operations are summarized in **Table 2**.

In the case of liquid injection, the precipitation vessel is pressurized by the addition of the SCF and then the liquid solution is injected into the vessel. The injected liquid solution is expanded by the dissolving SCF causing the solids to precipitate. In one variation of this type of operation, the liquid solution and the SCF antisolvent are continuously delivered to a

Figure 8 Experimental apparatus for a continuous liquid injection SAS process.

precipitation vessel in an apparatus similar to that shown in **Figure 8**. In this operation, solids precipitate continuously in the vessel, as the gas phase (SCF) leaves through a pressure-control valve. The valve also maintains the pressure inside the vessel constant. The ratio of the two flow rates (flow rate of the liquid solution and that of the SCF antisolvent), and the type of contact (co-current or countercurrent) can be important in the evolution of the precipitation process. Continuous precipitation using liquid injection has been given various acronyms such as precipitation by compressed antisolvent (PCA), aerosol solvent extraction system (ASES) and solution en-

hanced dispersion by supercritical (SEDS) fluid process. These processes have been carried out using slightly different precipitation procedures and in slightly different apparatus. At the end of the precipitation procedure, the vessel is washed with antisolvent to remove the liquid. This washing procedure is necessary because any liquid solvent remaining after depressurization could redissolve the solute.

Examples of solutes precipitated using liquid injection are summarized in **Table 3**. These examples include polymer microspheres, where the temperature of the precipitation vessel and the concentration of polymer in the solution play an important role in determining the morphology. There is a tendency for the polymer particles to agglomerate when the temperature is higher than the glass transition temperature of the polymer. Also, a high polymer concentration in solution produces fibres. On the other hand, micron-sized particles with a narrow size distribution can be obtained by adjusting the conditions of co-solvent and injection devices.

The liquid solution injection device plays a key role in SAS operations. The injector is designed to produce very small liquid droplets that expand in the precipitation vessel. Various geometries have been proposed to achieve this, including nozzles, capillaries, vibrating orifices and co-axial capillaries. The precipitation vessel must be designed to mix two phases and to

provide heating/cooling. Filtration of the particles at high pressures also requires special equipment.

In summary, both RESS crystallization and SAS crystallization appear to be promising methods for generating supersaturation and therefore represent alternatives to conventional crystallization. Such alternatives may prove attractive in applications such as polymer and pharmaceutical processing, or in particle design for drug delivery. It is possible to obtain a variety of morphologies and particle sizes in these processes by proper choice of conditions and expansion devices. However, *a priori* design of supercritical crystallization processes is not yet possible because the interaction between phase equilibria, expansion paths, and crystallization kinetics in these processes is not yet well understood.

Introduction

The transfer of extracted analytes to a chromatography column can be either offline or online. In offline analysis, the extracted analytes are collected and then an aliquot is manually transferred to the chromatography system. Online analysis is where the extracted analytes are automatically transferred to the analytical column. The intrinsic problems with offline collection are that sample loss and contamination are possible, the process is difficult to automate and the sample must be diluted with solvent to allow transfer, resulting in higher detection limits. Coupling extraction and chromatography minimizes many of these problems. Supercritical fluid extraction (SFE) and supercritical fluid chromatography (SFC) are ideally suited for coupling together as the most

frequently used solvent, carbon dioxide (CO₂), is the same for both techniques. In the case where pure CO₂ is used, the extracted analytes can be deposited at the start of the analytical column simply by reducing the pressure, and chromatography started by increasing the pressure again. Capillary SFC (cSFC) benefits particularly from online methods. The columns are small and easily overloaded, particularly with injection solvent. For example, a 1-μL injection occupies 0.5 m of a 50-μm i.d. column. Larger injections can easily cause band broadening and peak splitting. The limitation of injection size increases the detection limit. A logical method of solving the intrinsic problems of offline collection and cSFC is to link them online.

Samples for which SFE–SFC is Applicable

The main alternatives to SFC are GC and HPLC. Online coupling of SFE and HPLC is difficult, as the presence of gaseous CO₂ is incompatible with HPLC

analysis. If the analytes are thermally stable and volatile GC is the best separation technique to use. Many flavour and fragrance compounds in complex food samples should therefore be analysed by SFE-GC. The same is true of polychlorinated biphenyls (PCBs), pesticides and polyaromatic hydrocarbons (PAHs) in environmental samples.

When the sample contains thermally labile or reactive compounds, SFE-SFC is recommended. The procedure is excellent for thermally unstable polymer additives in commercial plastics or for fatty acids and triglycerides in food, etc. which cannot be analysed by GC very easily without derivatization. Natural products such as those containing terpene compounds or hops which contain highly reactive bitter compounds such as humulone and lupulone must also be analysed by SFC or HPLC as rearrangement can easily occur at elevated temperatures. Speciation studies on organotin, an important environmental pollutant, are difficult using GC or HPLC as derivatizations are required to increase volatility or provide a chromophore. Other application areas specific to SFC include the analysis of explosives and certain steroids, vitamins and other drug residues in biological samples. SFE-SFC finds important applications in environmental science. The analysis of pollutants in matrices such as soil and sediments, and extraction of sorbents on which pollutants in air or water have been selectively adsorbed have been analysed with this technique.

Capillary and Packed Column SFC

There are two broad categories of SFC, capillary and packed column. Capillary SFC was developed from capillary GC, and packed column SFC is more akin to HPLC. There are advantages to each. cSFC uses open tubular capillaries with bonded stationary phases. Compounds with differing solubilities in CO₂ are eluted using pressure programming, where the pressure, and hence density and solvent strength of the mobile phase is increased during the separation. This is the equivalent of temperature programming in GC. Use of modifiers is rare, partly due to difficulties of mixing at very low flow rates and partly because the 'universal' FID cannot be used with modifiers present. Open tubular capillaries offer little resistance to the flow of the fluid and columns can be long. A major problem with capillary SFC is the low sample capacity. The capillary columns are easily overloaded and very small injections are required, reducing sensitivity. Packed column SFC uses columns packed with HPLC packing materials. Small particles offer a high resistance to the fluid flow, and hence there is a pressure drop across the column. This results in a reverse

density gradient along the column, in which the fluid has the lowest solvent strength at the elution end of the column. This gradient is working against any pressure gradient applied, and can lead to precipitation of solutes. Elution in packed column SFC is now often controlled by addition of a modifier such as methanol rather than pressure programming. Use of modifiers means that the FID cannot be used, and detection for packed column SFC is more usually by UV absorbance detectors. However, modifiers allow more polar stationary phases to be used, which have much greater interaction with polar molecules. When CO₂ alone is used, the stationary phase must also be nonpolar, otherwise the solvent strength is not sufficient to elute polar compounds. The analyte interacts only poorly with both stationary and mobile phases, resulting in poor peak shape. The poor results with polar compounds on packed SFC columns has also been attributed to polar active sites (residual silanols) present on the silica. These are thought to be better shielded in coated capillaries. The solvent strength of modified CO₂ can be varied from similar to pentane for pure CO₂ to similar to acetonitrile with addition of 40% methanol.

The different natures of capillary and packed column SFC also lead to differences in instrumentation. The flow rates in cSFC are very low, and pressure is usually controlled by restrictors. These can be linear capillaries whose diameter and length can be adjusted to provide the required pressure. Adjustable, heated needle valves have also been used. The problem with whichever system is used is that the restrictor is a passive device, limiting mass flow at the pressure set by the pumps. Blockages can occur, and the flow rate is not well controlled. Flow rates in packed column SFC are much higher, which allows the use of manual or automatic back pressure regulators, which control the pressure independently of flow rate. Pressure, flow rate and solvent composition can, therefore, be much better controlled in packed column SFC. In reality, packed column and capillary SFC are very different techniques, with different areas of application.

SFE-SFC Interface

The analytes extracted during the SFE step can be introduced onto the analytical column in two main ways. The SFE extract can be passed through a sample loop and an aliquot directed to the SFC column, or the analytes can be trapped after the SFE and introduced onto the column in one go.

Aliquot Sampling

The simplest of interface for SFE-SFC is by aliquot sampling. A part of the extract is sampled by passing

it through an injection loop of the SFC system. A closed- or an open-loop system may be used. Closed-loop static SFE-cSFC involves the sample being sealed in an extraction cell for a period of static extraction. The extraction cell is connected to the sample loop of an injection valve. The analytes diffuse to the loop, and after equilibrium is reached the valve is actuated and an aliquot is injected into the SFC column.

The major advantage of this procedure is that small aliquots of the extract can be taken for consecutive analysis with virtually no difference in the extraction profile. However, a major disadvantage is that the solute containing extraction fluid has to reach equilibrium and diffuse out of the cell and into the injection valve before sampling is made. This can take many hours before complete equilibrium is attained. Recirculating pumps could be used to reach equilibrium in a shorter time, but these can easily become contaminated.

The system can be sampled more rapidly by allowing a portion of the extraction solution to pass through the loop to atmosphere, to flush the loop with fresh solution. A low-flow restrictor is connected to a valve inline after the injector, as shown in **Figure 1**. Static extraction can be carried out with the high-pressure valve closed. Opening this valve to the restrictor allows dynamic extract and filling of the sample loop. Actuation of the rotary valve passes the contents of the loop to the analytical column, and either static or dynamic extraction can be continued. This is known as open-loop SFE, and with this configuration one also has the opportunity of passing the sample through a detector (UV or FID). At periodic

intervals aliquots of the extract can be injected into the SFC column for analysis.

Aliquot sampling diverts only a small portion of the extract to the SFC column, and is therefore not suitable for quantitative SFC analysis. SFE-SFC with aliquot sampling is a good technique for basic qualitative investigation and for measuring fundamental parameters such as partition coefficients of solutes in supercritical fluids. However, it is limited in that it is not usually suited to quantitative or trace analysis where analytes in the whole extract must be accumulated prior to chromatographic analysis.

Trapping of Analytes

In contrast to static extraction with aliquot sampling, dynamic SFE-SFC operates principally by continuously exposing the analytes to a fresh stream of supercritical fluid. Extracted components are accumulated from this stream in a trap of some kind. Only after extraction is complete are the trapped analytes transferred to the SFC column for analysis. The major advantages of dynamic SFE-SFC are that it is much more rapid than static SFE-SFC and that trace analysis can be performed. The whole of the extracted material is passed to the SFC column, therefore the sensitivity is much greater than for offline analysis. **Figure 2** shows a schematic of a simple online SFE-SFC system. A high-pressure syringe pump supplies the extraction cell with fluid. The outlet of the cell is connected to a capillary flow restrictor which is connected to an accumulating trapping system. During extraction the depressurized gas from the restrictor passes through the trap and is then vented to the atmosphere through valve 1. The extracted analytes

Figure 1 Schematic of open-loop aliquot sampling system (A) Filling loop, dynamic extraction mode. (B) Injecting to column.

Figure 2 Schematic of SFE-SFC system.

are concentrated within the trap. After extraction is completed, valve 1 closes and valve 2 opens, switching the CO_2 onto the SFC column. The rotary valve switches the flow to the trap to avoid the cell and associated restrictor. This raises the pressure within the trap and the CO_2 becomes a supercritical fluid and capable of dissolving the trapped analytes and carrying them to the column.

If uncoated fused silica tubing is used to connect the trap to the analytical column (the retention gap), the analytes will, in theory, be unretained during the transfer. The pressure of CO_2 needed to effect the transfer need only be enough to provide some solubility of the analytes. Once they reach the stationary phase film of the SFC column they become concentrated as a narrow band, as the relatively low density solvent is not strong enough to elute the compounds from the stationary phase. After trapping is complete, the chromatography can be initiated using a pressure programme. If such phase ratio focusing occurs successfully, then good chromatographic efficiency is observed during the separation. If this process works well, the length and internal diameter of the retention gap do not significantly affect the resolution.

Other more complicated systems have been reported using on-off and multiport switching valves to allow continuous extraction or to permit the extraction cell to be vented during simultaneous chromatographic analysis. The 'plumbing' of such a system can be constructed to any specific requirement.

Since analytical SFE is most often performed with fluids that decompress to gases at ambient conditions (such as CO_2 , 1 mL min^{-1} of which produces a gas flow of approximately 500 mL min^{-1}), the success of trapping depends on the success of recovering the analytes from the expanded gas. Fast flow rates tend to elute volatile analytes from the trap, thus, for quantitative results, recovery of extracted components should be performed at lower flow rates. The problem of loss of volatile analytes is often not severe in SFE-SFC, as these are likely to be analysed by SFE-GC. Therefore SFE-SFC traps generally need be more concerned with trapping less volatile materials.

Trapping procedures

There are several methods of trapping extracted components from dynamic SFE in preparation for online SFC analysis. The requirements are to efficiently trap all the material from the gas or low-pressure stream from the extractor, and then to release all the components when the flow is switched to the analytical column. Two methods are used for this:

- cryogenic trapping; and
- trapping on an adsorbent stationary phase; the stationary phase can be either on particles packed into the trap, or coated onto a fused silica capillary.

Cryogenic trapping

Trapping on uncoated fused silica retention gaps A length of uncoated fused silica capillary can be cooled by expanding CO_2 . Solutes passing through the capillary in the depressurized gas stream from the SFE will be trapped in the cooled section. The cooling can then be switched off, and the section pressurized with CO_2 to redissolve the analytes. **Figure 3** shows an arrangement for a cryogenically cooled fused silica trap. In this arrangement the expanded mobile phase from the extraction cell is released from a different outlet than the incoming CO_2 for the SFC. This minimizes contamination of the system from previous analyses. The extracted analytes are in contact only with deactivated fused silica after leaving the extraction cell, which reduces loss of polar analytes by adsorption on metal surfaces.

The flow rate of the expanding extraction fluid and the temperature at which analytes are trapped markedly affect the recoveries obtained when uncoated fused silica tubing is used. In many systems, linear extraction restrictors are used, since they provide the correct flow rate range for online coupling with capillary SFC. They also tend not to plug as quickly as other restrictors when used for SFE. The length and internal diameter of the capillary restrictor tubing

Figure 3 Cryogenically cooled trap.

and the pressure at which the extraction is performed should therefore be considered to obtain suitable flow rates.

Restrictors with internal diameters greater than 30 μm result in higher extraction efficiencies, but lower recoveries and significant band broadening of more volatile components. However, restrictors with internal diameters less than 15 μm do not allow sufficient flow for efficient extractions over a short period of time, but yield good chromatographic peak shapes. As a rough guide, the gaseous flow rates from 15-cm lengths of 15-, 20-, 25- and 30- μm restrictors at a pump pressure of 300 atm are, approximately, 80, 150, 240 and 300 mL min^{-1} , respectively. A good compromise therefore is to use a restrictor with a flow rate of 100–200 mL min^{-1} . Lengths of capillary tubing of 20 or 25 μm i.d. are suitable for most needs.

The trapping efficiency is also strongly dependent on the trapping temperature. The higher the temperature, the more volatile components will be lost from the trap. Cooling in the region of -40°C to -60°C will allow trapping of C_{10} hydrocarbons with reasonable efficiency. The trap should only be cooled to a sufficient temperature to trap the analytes of interest, as too low a cryofocusing temperature may result in restrictor plugging, or components, such as water, freezing in the restrictor. This reduces the rate of extraction and makes it difficult to reproduce analyses. An alternative arrangement for trapping volatile substances is to keep the restrictor hot and deposit the analytes in the transfer line held in a cryogenically cooled oven as shown in Figure 4.

The use of micropacked columns has also been reported. In this case the restrictor can be vented onto the head of the analytical column. The cooling of the expanding gas cools the column and the analytes are deposited on the packing at the start of the column.

Trapping on coated fused silica retaining pre-columns
An alternative to the cryotrapping method is the use

Figure 4 Arrangement for keeping restrictor hot and trapping in cryogenically cooled oven.

of a coated fused-silica retaining pre-column for concentrating extracted solutes. Compared to uncoated fused silica, coated columns such as GC columns are much more effective at trapping. The key is to trap effectively, but allow the mobile phase to elute the trapped materials during the pressure programme. It is likely that a column coated with a similar material to the analytical column will be effective. The phase thickness on the column is also important, thicker phases having a greater trapping power. This method allows the trapping at room temperature using widely available bonded-phase GC columns.

Trapping on sorbent traps Sorbents may also be used as an effective method of trapping. This entails the use of short traps (usually 2 cm in length) packed with organic sorbents such as Tenax-GC, Carbotrap or with HPLC packing materials. Bonded silica and polymeric stationary phases designed for solid-phase extraction (SPE) are available with a wide variety of functionality, and would make ideal packing material for this application. These materials will effectively trap the analytes from the low-pressure gas stream, and can then be desorbed by high-pressure supercritical CO_2 . The considerations are similar to those when using coated silica columns. It is important when using such a system that breakthrough of the analytes from the sorbent does not occur and also that the desorption behaviour is suitable for online chromatographic analysis. Desorption is performed by increasing the trap temperature or by using the supercritical fluid to desorb the sample. The process is effectively the same as SPE, with supercritical CO_2 as the desorbing solvent. The stationary phase should be selected to have a strong enough affinity to trap the analytes from the gas stream, but to be desorbed by supercritical CO_2 . Supercritical CO_2 is essentially non-polar, and it is unlikely that polar compounds could be eluted from polar stationary phases. It is not always possible to elute all the trapped analytes with CO_2 , and supercritical nitrous oxide has been found to be more effective than supercritical carbon dioxide in removing solutes from adsorbents. However, the oxidizing nature of this material has resulted in explosions, and is not recommended. It is therefore more important to select the most appropriate stationary phase which will trap the analytes, and then be desorbed by the mobile phase.

Use of Modifiers and Solvent Venting

Although CO_2 is a versatile extraction solvent, sometimes modifiers are needed to solvate particular analytes or overcome analyte–matrix interactions.

This presents a problem in SFE-SFC. With cryogenically cooled traps, the modifier will be trapped and block the restrictor, or flood the column when the flow is switched to the analytical column. If the modifier becomes liquid after depressurization, it will dissolve the analytes and elute them from coated traps. Coated capillaries can be used to trap the analytes, provided the modifier is present at a sufficiently low concentration to remain as a vapour in the CO₂ gas stream. Therefore the upper limit for the modifier addition is that at which CO₂ is saturated at atmospheric pressure and the trapping temperature. For methanol the maximum addition at 25°C is 14%. It is important that the pressure in the trap does not rise, as this may cause the modifier to liquefy. Wide-bore coated capillaries may be needed for the trap to reduce back pressure, and a second, narrow-bore column will catch any breakthrough from the wide-bore trap. A short gas purge will remove any residual modifier, and the analytes can then be transferred to the analytical column dissolved by supercritical CO₂. It may be necessary to introduce a refocusing trap, which will focus the analytes from the supercritical CO₂, as the trap volumes may be quite large, which would otherwise lead to band broadening.

Apart from use of modifiers, other situations occur when large amounts of solvent are trapped with the analyte. Co-extraction of low-molecular-weight solvents or reactants along with the desired analytes is one example. Provided the co-extractant is sufficiently volatile and the analyte involatile, then the unwanted material can be removed from the intermediate trap by gas purge. The analytes can then be transferred to the analytical column with supercritical CO₂.

SFE as a Sample-Introduction Technique

As stated previously, one of the problems of cSFC is sample introduction without flooding the column with solvent. Aqueous samples are a problem for capillary and packed-column SFC, as water is only slightly soluble in CO₂. SFE can be used as a solventless sample introduction technique to avoid this problem. One method to achieve this is to inject the sample onto a pre-column fitted with a restrictor. The solvent will flood the column for some distance. The solvent can be removed by gas purging, leaving the less volatile analytes behind. The entire pre-column is then pressurized with supercritical CO₂ to dissolve the analytes and carry them to the analytical column. In effect, the pre-column is acting as an SFE cell. Samples dissolved in aqueous media can be concentrated and transferred to packed or capillary columns

while maintaining high efficiency. The use of solid sorbents has proved very useful in sample introduction to SFC. The dissolved analytes are injected onto a sorbent, the solvent can then be removed by evaporation and the analytes transferred to the analytical column using SFE-SFC. The whole process has been called SPE-SFE-SFC. This method is particularly applicable to biological samples where the analyte has no chromophore. These are often thermally labile, and therefore analysis by GC or HPLC is problematical. Direct sample introduction to SFC is also a problem due to the aqueous nature of the samples. Use of an intermediate trap and solvent purging to remove the water and introduce the analytes to the SFC column allows much larger samples to be introduced, improving sensitivity by a factor of 100 or more. In environmental analysis, samples of several hundred millilitres can be passed through a solid-phase extraction cartridge to concentrate impurities. The cartridge can then be eluted with CO₂ to the analytical column. This system could also be used as an HPLC-SFC interface.

Optimization of Conditions for SFE-cSFC

A number of parameters must be optimized for successful analysis by coupled SFE-cSFC. Principal among these are the conditions for quantitative extraction. This should begin with a determination of the supercritical fluid extractability of the analyte(s) from the non-sorptive matrices (filter paper, etc.) to assess the appropriate solvent, density and temperature conditions. Trial runs on spiked samples then allow investigations of matrix-solute interactions; if necessary these may be overcome by a period of static extraction. The kinetics of extraction must then be determined in order to define the required extraction time.

Factors affecting the efficiency of intermediate trapping must then be addressed. The nature of the analyte is crucial, while the possible presence of co-extracted, interfering compounds demands either selectivity during extraction, or the trapping on an adsorbent from which selective desorption into the SFC column is possible. The sample size must be carefully chosen so that the capacity of the SFC column is not exceeded, and the extracting supercritical solvent must be of sufficient purity to avoid introduction of extraneous material into the column. Finally, the conditions for efficient SFC analysis must be optimized, preferably offline. Correct choice of column, temperature and pressure/density programme are vital. Compromises may be inevitable if the extracted analytes have a range of polarities.

Conclusion

Coupled SFE-SFC has shown itself to be a very useful technique for those samples for which it is applicable. The ability to transfer all the extract to the analytical column without manipulation increases sensitivity, reduces contamination and sample handling. The overloading of capillary columns is avoided. Now that methods for using modifiers in the extraction solvent and SFE sample injection methods have been developed, there is every likelihood that SFE-SFC will become a more widely used technique.

SUPERHEATED WATER MOBILE PHASES: LIQUID CHROMATOGRAPHY

R. M. Smith, Loughborough University,
Loughborough, Leics, UK

Copyright © 2000 Academic Press

At room temperature, water on its own is an unattractive solvent in liquid chromatography. In reversed-phase chromatography, water is a weak eluent and is often regarded as an inert component of the mobile phase. It is mainly used to dilute a stronger organic component and thus control the overall eluent strength. In contrast, in normal-phase chromatography, water is a powerful eluent and interacts strongly with the stationary phase, often deactivating it. Even trace amounts in a nonpolar eluent (or even in a sample) will markedly alter the retention properties of a silica surface. In separation methods aqueous eluents are used primarily for ion exchange chromatography or for the size exclusion separation of biological molecules.

However, this represents the situation at room temperature and atmospheric pressure. When liquid water is heated under pressure, its dielectric constant, viscosity and surface tension all decrease. These changes in the properties of water are well known but have largely remained the province of the physical chemist and chemical engineer. They have been widely studied because of the importance of water as a heat transfer agent and they play their part in the design and construction of steam power generation

plant and in related areas. Above 374°C under a pressure of 221 bar, a single supercritical phase is obtained. Although these conditions seem extreme for the laboratory, they occur in nature in the ocean depths at the spreading points in the earth's crust where water issues from fumeroles at 350–400°C and 250 bar.

In recent years organic chemists have been attracted by the possibility of using superheated or supercritical water to achieve clean solvent-free conditions and to generate novel reaction conditions which are not available at room temperature. It has also been employed as a solvent for the high temperature oxidation for waste remediation or for the destruction of hazardous materials such as nerve gases and explosives as an alternative to high temperature incineration. In inorganic chemistry, supercritical water has been used as a solvent to enable high temperature reactions to be carried out without the inconvenience of using molten salts.

However, the analytical chemist has made little use of water under pressure, although the potential of supercritical water as a fluid solvent for chromatography was recognized by Lovelock in 1958. Some work has exploited steam as a mobile phase in gas chromatography, but the condensed phase has largely been ignored. Although liquid chromatographers have used elevated temperatures to improve separations or efficiencies, in almost every case the composition of the organic-aqueous eluent was kept

Figure 1 Change in dielectric constant of water with temperature.

constant and only the effect of the temperature was studied, typically up to 70–80°C.

Recently, the changes in the properties of liquid water above 100°C have attracted the interest of the analytical chemists, who have recognized that these low polarities might provide an environmentally clean solvent for extraction. Subsequently, the use of superheated water has also been applied to liquid chromatography. Some of the published papers have referred to this region of the phase diagram as subcritical water but this could imply any temperature less than 374°C. This review will instead employ the expression superheated water, which is defined as water held as a liquid under pressure between 100°C and the critical point.

Properties of Superheated Water

As the temperature of water is raised under a sufficiently high pressure for it to remain in the liquid state

there is a steady decrease in its dielectric constant (Figure 1) from about 80 at room temperature to less than 25 at 300°C. These changes represent a marked change in the solvent polarity of the water. By 250°C the dielectric constant of water is about 30, which is less than that of methanol at room temperature, so that even under conditions well below its critical point, water will resemble the polarity of common organic solvents used as eluents in reversed-phase liquid chromatography. There is also a decrease in the viscosity of water from 1.0 cp at room temperature to 0.28 cp at 100°C, as well as in the surface tension.

The pressure conditions usually needed to carry out supercritical fluid chromatography (SFC) with carbon dioxide can be as high as 300–500 bar in order to achieve a sufficiently high density to provide a reasonable solvent strength. However, the vapour pressure of water (Figure 2) is modest and even by 200°C only reaches 15 bar, so that only moderate pressures are required to maintain a liquid state. In addition, the density of hot liquid water changes by only a small amount with changes in the applied pressure. The solvation properties are thus effectively independent of pressure. This is in marked contrast to supercritical carbon dioxide where pressure control is critical because of its marked effect on density.

Application in Analytical Extractions

The first serious analytical chemistry interest in the potential of water under pressure above 100°C came in 1994, when Hawthorne and colleagues investigated the extraction of organic pollutants from environmental solids with supercritical and subcritical water. They had been prompted by reports that the solubility of benzo[*a*]pyrene increases from 4 ng mL⁻¹ under ambient conditions to approximately 10% by weight

Figure 2 Change in vapour pressure of water with temperature.

at 350°C and 100 bar. This represents an increase in solubility of about 25 million. They found considerable solubility for polar analytes, such as chlorinated phenols, and even a significant solubility for nonpolar analytes, such as naphthalene at 50°C. Raising the temperature resulted in an increased solubility for polynuclear aromatic hydrocarbons (PAHs) and by 250°C all their test compounds except the *n*-alkanes had been completely extracted. The alkanes required supercritical conditions and were completely extracted at 400°C. These results confirmed that superheated water had a sufficiently high solubilizing power to be used as a solvent for even nonpolar analytes. They then demonstrated that subcritical conditions of 250°C and 50 bar would also efficiently extract PAHs from soil samples. In addition, good recoveries were obtained from air particulates. These results also showed that pressure was not an important factor, in marked contrast to the pressure dependence of supercritical fluid extraction with carbon dioxide.

Subsequently they studied the extractions further and showed that polychlorinated biphenyls (PCBs) could be extracted from soils and sediments with subcritical water. At 300°C and 50 bar, complete extraction could be achieved in pure water. Other workers have found that water can be used for the extraction of PCBs from a range of matrices in good yield. In a similar study, the pesticides Dacthal and acid metabolites have been extracted from soil with superheated water.

Chromatography using Superheated Water as the Mobile Phase

It was realized that if superheated water could extract PAHs from soils and dissolve PCBs, then it

was behaving as a less polar solvent than the methanol–water and acetonitrile–water mixtures conventionally used as mobile phases in reversed-phase liquid chromatography. It should therefore be possible to use superheated water as a mobile phase and achieve typical reversed-phase liquid chromatographic separations. Many studies have examined the effect of increasing the temperature on separations and have shown that there is a consistent drop in retention with an inverse relationship to the absolute temperature (k varies as $1/T$ K). However, most of this work has either looked at temperature effects using constant eluent composition or has been limited to 80–90°C by the volatility of the organic components of the mobile phase.

In 1996, Smith and Burgess demonstrated that under a modest pressure it was possible to carry out the reversed-phase separation of phenols using superheated water at 160°C on a polystyrene-divinylbenzene (PS-DVB) column. The equipment was a combination of high performance liquid chromatography (HPLC) and gas chromatography (GC) systems (Figure 3) with some components from a packed-column SFC system. The water mobile phase was pumped using a single reciprocating pump but, unlike SFC, there was no need to cool the pump heads to condense the mobile phase. As the mobile-phase polarity can be controlled by temperature, no modifier pump was needed. The column was heated in a GC column oven which enabled the temperature to be controlled up to 350°C. To maintain the pressure a SFC back-pressure regulator was used. A detector fitted with a high pressure flow cell was originally employed but, because the back-pressures required are relatively low, in later studies standard HPLC spectroscopic flow cells were used for fluorescence

Figure 3 Superheated water chromatograph. Components: 1, pump; 2, injection valve; 3, preheating coil; 4, column; 5, detector; 6, back-pressure regulator.

and ultraviolet-visible spectroscopy. It is also possible to replace the back-pressure regulator with a length of narrow-bore PEEK tubing.

A PS-DVB packed column was used in the first studies because this material can be used without problems in size exclusion chromatography at 160°C and is thermally stable at this temperature. Phenols were examined with a methanol–water eluent and then the methanol content was reduced while raising the temperature in steps. With each increase in temperature the retention times decreased. By 180°C in the absence of methanol, the samples had similar retention times to those in 20 : 80 acetonitrile–water at room temperature.

The relative retention of a wide range of analytes from phenols, amides, esters to simple aromatic compounds demonstrated that the retention followed a similar pattern to conventional reversed-phase liquid chromatography. The separation followed the hydrophobicities of the analytes and the homologous parabens eluted in order of increasing chain length. They were also stable, showing neither hydrolysis nor oxidation. The separations, as expected, were insensitive to the back-pressure applied to the column.

It was also realized that programming the temperature of the column during the separation would systematically reduce the eluent polarity. This produced an effect similar to gradient elution, and would speed up and focus later peaks. Inorganic buffers could also be added to control the pH without causing any problems.

Stationary Phases for Superheated Water Chromatography

Most of the work that has been reported has employed PS-DVB columns which have shown reasonable temperature stability. They can be used up to about 220°C before softening appears to reduce their lifetime. As in ordinary HPLC, these columns show a marked difference in the retention of nonpolar and hydrogen-bonding analytes. The latter, including alcohols and phenols, have markedly lower retentions than nonpolar analytes such as alkylbenzenes and nitrobenzene. These latter compounds cannot be easily eluted even at 230°C.

Porous graphite carbon (Hypercarb) has been examined as an alternative thermally stable stationary phase. No instability was observed and the separations of mixtures of phenols, anilines and aryl amides were similar to those obtained at room temperature with conventional eluents (Figure 4).

There is particular interest in octadecylsilica (ODS)-bonded silica phases because of their widespread use in conventional liquid chromatography.

Figure 4 Separation of amides on porous graphitic carbon column at 190°C. Analytes: 1, benzenesulfonamide; 2, benzamide; 3, *m*-toluamide.

However, although a number of different silica-based bonded-phase materials have been examined, they all show quite rapid degradation at temperatures greater than 100°C. Even though they have a lower retention capacity than the PS-DVB columns and do not require such high temperatures to obtain elution, it appears that this matrix is insufficiently stable for routine use.

A second problem was that, when highly end-capped ODS-bonded materials were examined with 100% water as the eluent, the octadecyl chains collapsed on to the silica surface on cooling the column to room temperature. As a result, the retention capacity of the column dropped markedly and this was not restored by heating. Instead, the column had to be treated with methanol–water mixtures. Similar problems have been reported in reversed-phase liquid chromatography at room temperature when the mobile phase contains less than 2% methanol.

A promising alternative stationary phase is polybutadiene-coated zirconia, a relatively new material, which is reported to be stable in water at 200°C. It gives good separations and peak shapes. The order of elution is similar to that on ODS phases in conventional reversed-phase liquid chromatography.

The elevated temperatures would be expected to reduce mass transfer effects in the mobile phase because of higher diffusion rates and this would result in improved separation efficiencies. Van Deemter curves of column plate heights against mobile-phase flow rate of water at elevated temperature determined for the PS-DVB and Hypercarb columns have been compared with acetonitrile–water separations at room temperature. In both cases, at the optimum flow rates the height equivalent to one theoretical plate (HETP) values are similar, but in superheated water the efficiency decreases rapidly at lower flow rates. This

effect can be ascribed to a higher diffusion rate in the mobile phase at the higher temperature.

Detection in Superheated Water Chromatography

One of the advantages of superheated water chromatography is that it increases the possible number of detection methods that can be employed compared to liquid chromatographic methods using an organic solvent. However, with some detectors the mobile phase had to be cooled to room temperature to avoid baseline instability due to refractive index effects. So far no problems have been experienced due to the analytes coming out of solution between the column and detector, probably because the concentrations are generally low and the transfer time to the detector is brief.

Because usually only low back-pressures (less than 50 bar) are required to maintain the liquid state in the column, standard liquid chromatography flow cells can frequently be employed for ultraviolet-visible and fluorescence spectroscopic detection. Alternatively, high pressure ultraviolet-visible flow cells designed for SFC application can be used. In both methods of detection, one advantage of water as an eluent is that it is transparent down to 190 nm. This enables low wavelength detection of unconjugated double-bond chromophores without solvent interference. However, some fluorescence detection is reduced compared to organic solvents because of quenching by the polar aqueous solvent.

The absence of an organic modifier raised the possibility that the eluent could be passed to a flame ionization detector. This could provide a simple method of universal detection for liquid chromatography, which previously has only been obtainable using mass spectrometry. This possibility was realized by Miller and Hawthorne, who demonstrated the use of the FID in 1997 to detect alkanols, phenols and amino acids, and confirmed by others.

Another detector that has problems in conventional liquid chromatography, because of mobile phase interference, is on-line nuclear magnetic resonance spectroscopy (LC-NMR). Many of the problems can be overcome by employing superheated heavy water (deuterium oxide) as the mobile phase. Compared to deuterated organic modifiers, deuterium oxide is relatively cheap and unlike supercritical fluid chromatography the flow cell can be at room temperature and pressure. This makes stop-flow detection easier and characteristic proton-NMR spectra have been obtained for a range of compounds, including barbiturates, sulfonamides and a number of pharmaceuticals and natural products.

It has also been demonstrated that superheated water chromatography can be linked to mass spectrometry using a standard LC-interface to give a superheated water LC-NMR-MS system. These separations using superheated deuterium oxide have also provided some interesting exchange reactions which are more selective and specific than those reported with supercritical deuterium oxide.

Application of Superheated Water Chromatography

A wide range of analytes (Table 1) has been examined by superheated water chromatography. They have generally been moderately polar and could be characterized as analytes where conventional liquid chromatography would employ a mobile phase with 60% or less organic modifier. Less polar analytes, such as alkylbenzenes, can currently cause problems because they require a mobile-phase temperature above the limit of the polymeric stationary phases primarily used so far.

The principal groups of compounds examined so far have been phenols (Figure 5), alcohols, amino acids, esters, pharmaceuticals, water-soluble vitamins and lactone natural products. The method is still relatively new and further applications are constantly being developed. Although there was concern that the separation conditions might cause sample oxidation, hydrolysis or degradation, so far few compounds have caused problems. Not surprisingly, aspirin is hydrolysed but this occurs readily even at room temperature. Nitrobenzene appears to degrade and there is some suggestion that other nitro-compounds are also thermally unstable in hot water. In contrast, compounds such as the parabens (4-hydroxybenzoate

esters) which might be thought to be susceptible both to oxidation and to hydrolysis, have been separated without difficulty. One reason may be that, as the temperature is raised and the water becomes less polar, it also becomes a weaker hydrolysis agent.

Introduction

‘Surfactant’ is a contraction of ‘surface active agent’. It has come to be used interchangeably with

detergent, particularly when applied to cleaning products such as fabric washing powders, soaps, hard-surface cleaners and the many other products used for cleaning in and around the home. Solutions of surfactants exhibit one or more of the properties of detergency, foaming, wetting, emulsifying, solubilizing and dispersing.

This article will deal with the main classes of surfactants used as commercial detergents, which are not single compounds but mixtures of compounds of the same general structure but having a range of alkyl chain lengths. Surfactants have the follow-

ing general properties:

- They are molecules composed of groups of opposing solubilities, typically an oil-soluble hydrocarbon chain and a water-soluble ionic group.
- They are soluble in at least one phase of a liquid system.
- They form oriented monolayers at phase interfaces.
- They form micelles (aggregates of molecules or ions) above a limiting concentration in solution.

Chromatographic separations are important in surfactant analysis for a number of reasons. The most important of these is based on their ability to separate both molecules of different, though similar, structures and molecules from within a structural family on the basis of carbon chain length, chain branching or positional isomer distribution. Many procedures for surfactant analysis give average values for the property determined. Two quite different examples are titrimetric determination of the active level of a surfactant which requires a value for the mean molecular weight of the surfactant to calculate the weight percent of active material and determination of the degree of ethoxylation of an alcohol or alkylphenol ethoxylate by proton nuclear magnetic resonance, which gives a value for the average degree of ethoxylation but no information on the ethoxamer distribution. Chromatographic techniques can supply the mean molecular weight to use with the titration and both the detailed ethoxamer and alkyl chain length distribution of the ethoxylate. Such detailed knowledge of molecular composition is required for full understanding of surfactants and their properties.

Other areas of surfactant analysis in which chromatographic techniques are used are determination of levels and composition of surfactants in products and in the environment, particularly in studying decomposition, and in studying the detailed composition of the surfactant itself including low levels of impurities or contaminants which may result from the manufacturing process. Legislative and consumer pressures for cleaner, safer, more environmentally friendly raw materials and products are resulting in such analyses becoming increasingly common.

In the following sections, the most common surfactants in the detergents and related industries and the chromatographic techniques (gas-liquid chromatography, high performance liquid chromatography, supercritical fluid chromatography, thin-layer chromatography, capillary electrophoresis) used in their analysis will be described. The examples have been chosen to illustrate the variety of sample preparation, separation and detection procedures which can be used.

Anionic Surfactants

Alkylbenzenesulfonates

Alkylbenzenesulfonates are the most common of the commercial anionic surfactants. Their general structure is *p*-alkylbenzenesulfonic acid, sodium salt (**Figure 1**) where the alkyl chain may range from C9 to C14 with the benzenesulfonate moiety attached in different proportions at each carbon atom from C2 to the central carbon of the chain. The carbon chain is essentially linear to permit biodegradation, though there is a minor usage of branched alkylbenzenesulfonates for specific applications.

Gas chromatography Gas chromatography (GC) of alkylbenzenesulfonates requires some pretreatment of the molecule to enable it to be volatilized. The most common pretreatments are desulfonation and derivatization. The following examples demonstrate a number of sample preparation and detection options:

- Desulfonation of alkylbenzenesulfonate with phosphoric acid to the corresponding linear alkylbenzene (LAB) followed by separation on a fused silica capillary column (**Figure 2**). This procedure enables both the alkyl chain lengths and the attachment points of the benzene ring along the chain to be determined.
- Desulfonated linear alkylbenzenesulfonate (LAS) or LAB can be prefractionated from complex detergent and environmental samples using argentation thin-layer chromatography (TLC), in which the TLC plate is coated with silver nitrate to modify the separation process. The separated spots are recovered from the plate and analysed using similar conditions to those in **Figure 1**. Electron impact mass spectrometry (EIMS) detection is used to give component identification.
- LAS and dialkyltetralinsulfonates are converted to their sulfonyl chlorides by reaction with phosphorus pentachloride and then to their trifluoroethyl derivatives by reaction with trifluoroethanol. These derivatives are separated using similar conditions to those described in **Figure 2**.

- Aqueous solutions of LAS are shaken with tetrabutylammonium hydrogensulfate to form ion pairs. Injection of the ion-pair solution into a GC injection port at 300°C forms the butylsulfonate derivatives of the LAS which are separated on a HP-5 column (20 m \times 0.2 mm i.d., 0.33 μ m film) programmed from 110°C to 220°C at 10°C per minute then 300°C at 6°C per minute with a final 3-minute hold. Detection is by EIMS to give full spectral information.
- LAS is rapidly and efficiently converted to its methylsulfonate ester by derivatization with trimethoxyorthoacetate at room temperature and separated as in Figure 3.

High performance liquid chromatography The advantage of high performance liquid chromatography (HPLC) for the separation of LAS is that, in contrast to GC, sample preparation specifically to make the

LAS compatible with HPLC is unnecessary. LAS can be determined by HPLC by a number of procedures of which examples to demonstrate different separation and detection conditions are given below.

The chain-length distribution of LAS can be determined on a column (300 \times 3.9 mm) of μ -Bondapak C18 (10 μ m) using a linear gradient from 70 : 30 acetonitrile–0.15 mol L⁻¹ sodium perchlorate solution to 90 : 30 of the two solutions. UV photometric detection is at 230 nm. Peaks are eluted in order of increasing alkyl chain length.

The positional isomer distribution is determined using a column (250 \times 4 mm i.d.) of Spherisorb ODS II (3 μ m) with an isopropanol–water–acetonitrile gradient with 0.02 mol L⁻¹ sodium perchlorate added and UV detection at 225 nm.

Both chain length and positional isomer distribution can be obtained using a Zorbax ODS column (250 \times 4.6 mm i.d.) with a gradient from acetonitrile–water

Figure 3 Chromatogram of methyl esters of C10–C13 linear alkylbenzene. Column 25 m \times 0.2 mm i.d. fused silica capillary of HP1 (0.33 μ m film) programmed from 120°C to 240°C at 3°C per minute, final temperature held 20 min, injector and detector at 275°C, FID, carrier helium at 1 mL min⁻¹, splitless injection. (40 : 60) + 100 mmol L⁻¹ sodium chloride to acetonitrile–water (60 : 40) with UV photometric detection at 225 nm.

Other separation techniques The analysis of LAS using a silica gel G layer (a standard TLC silica) impregnated with 10% ammonium sulfate and 2-methyl-4-pentanone–propyl alcohol–0.1 mol L⁻¹ acetic acid–acetonitrile (20 : 6 : 1.6 : 1, v/v/v/v) and visualization by spraying with phosphomolybdic acid in ethanol followed by charring by heating has been described.

Supercritical fluid chromatography has been used for analysis of alkylbenzenesulfonates on a fused silica open tubular column (10 m \times 0.53 or 0.25 mm i.d.) coated with a 0.1 or 0.2 μ m film of SE54 with carbon dioxide as mobile phase and FID detection. The LAS is derivatized before analysis.

Capillary electrophoresis can be used for the separation of LAS by alkyl chain length. Conditions are a fused silica capillary (60 cm \times 50 μ m i.d., 40 cm to detector) with a buffer of acetonitrile–water (40 : 60), 3.0 mmol L⁻¹ magnesium ion, pH 6.0, 10 mmol L⁻¹ sodium acetate. Applied voltage is 30 kV and detection is by UV at 220 nm.

Alkyl Sulfates

Alkyl sulfates normally exist as a group of compounds with a range of alkyl chain lengths (Figure 4).

They can be readily determined by GC following acid hydrolysis, recovery of the parent alcohols, and separation either as the alcohols or after conversion of the alcohols to their trimethylsilyl ether derivatives. Typical conditions are a 10 m \times 0.53 mm i.d. column of methylsilicone phase programmed from 70°C to 240°C at 5°C per minute with helium as carrier and FID. The HPLC separation of alkyl sulfates by carbon chain length uses a column 25 cm \times 4.6 mm i.d. ODS material with gradient elution from 60 to 30% aqueous acetonitrile containing 0.01 mol L⁻¹ disodium hydrogenphosphate and 0.01 mol L⁻¹ sodium nitrate. Detection is at 242 nm. This is an example of inverse photometric detection where nitrate in the mobile phase absorbs a constant level of radiation apart from when the level of nitrate is reduced by the presence of the non-absorbing alkyl sulfate anion. It is the reduced absorbance which is monitored.

Alkyl sulfates can be separated on a synthesized cross-linked amine-fluorocarbon polymer on silica column with 0.2 mmol L⁻¹ naphthalenedisulfonate–35% acetonitrile mobile phase. Both indirect conductivity and indirect photometric detection can be used.

TLC separation of alkyl sulfates and alkyl ether sulfates using a silica gel layer with acetone–tetrahydrofuran (9 : 1, v/v) and visualization with Pina-cryptol Yellow has been described.

Alkylethoxy Sulfates

Alkylethoxy sulfates (AES) have the general formula $\text{CH}_3(\text{CH}_2)_n(\text{OCH}_2\text{CH}_2)_m\text{SO}_4\text{Na}$ where n is commonly in the range 9 to 17 and mean values of m are in the range 2 to 20 (Figure 5). They are formed by reaction of alcohols with ethylene oxide to give a desired molar ratio of ethoxylate though in practice they are a broad distribution of ethoxylate ratios peaking at the desired mole ratio. The alcohol ethoxylate is subsequently sulfated.

The hydrophobe (alkyl chain) distribution of alkylethoxylated sulfates can be obtained through GC by reaction of the AES with 30% HBr in glacial acetic acid at 90°C overnight to give alkyl bromides followed by separation on a column (6 ft \times $\frac{1}{8}$ in o.d.) of 10% OV-17 on Chromosorb W with temperature programming from 100°C to 250°C at 8°C per minute with helium as carrier gas and FID. AES can be analysed by HPLC on a 2.5 cm \times 2 mm i.d. column of C18 reversed-phase material with a water–tetrahydrofuran gradient system. The detector is the evaporative light-scattering detector as the molecules being separated have no strong chromophore. There are a number of alternative gradient systems.

To obtain more detailed distributions by either GC or HPLC, the molecule can be desulfated and analysed as described below for ethoxylated alcohols.

Sulfonates

As for alkyl sulfates, alkylsulfonates exist in a range of alkyl chain lengths with the added complication that they can be primary, secondary or α -olefinsulfonates and also mono- and disulfonates with hydroxy and -ene substitution (Figure 6).

Alkylsulfonates are separated by HPLC on a synthesized cross-linked amine-fluorocarbon polymer or silica column with 0.2 mmol L⁻¹ naphthalenedisulfonate–35% acetonitrile mobile phase. Both indirect conductivity and indirect photometric detection can be used.

Separation of positional isomers of alkylmonosulfonates is obtained using Hypersil ODS I phase with

acetonitrile–water gradient and *N*-methylpyridinium chloride as visualization reagent for indirect photometric detection. Baseline separations are obtained.

As for LAS, aqueous solutions of secondary alkanesulfonates (SAS) can be shaken with tetrabutylammonium hydrogensulfate to form ion pairs. Injection of the ion-pair solution into a GC injection port at 300°C forms the butylsulfonate derivatives of the SAS which are separated using on an HP-5 column (20 m \times 0.2 mm i.d., 0.33 μ m film) programmed from 110°C to 220°C at 10°C per minute then 300°C at 6°C per minute with a final 3-minute hold. Detection is by EIMS to give full spectral information.

The separation of α -olefinsulfonates (AOS) into their hydroxy, alkene, and disulfonate isomers together with chain length information is achieved using a column (25 cm \times 4.6 mm) of Zorbax TMS with a mobile phase of methanol–water (75 : 25, v/v) and refractive index detection. This separation has also been demonstrated at an operating temperature of 55°C.

An alternative column for separation of AOS by carbon chain and isomer is a Novapak Phenyl column (150 \times 2 mm) with a mobile phase of 70 : 20 : 10 10 mmol L⁻¹ ammonium acetate–acetonitrile–tetrahydrofuran (THF) at 0.2 mL min⁻¹ with full-scan MS detection to confirm peak identification. Supercritical fluid chromatography has been used for analysis of alkylsulfonates on a fused silica open tubular column (10 m \times 0.53 or 0.25 mm i.d.) coated with 0.1 or 0.2 μ m SE54 with carbon dioxide as mobile phase and FID detection. The sulfonates are derivatized as described above for LAS before analysis. Capillary electrophoresis can be used to separate C4 to C12 alkanesulfonates by alkyl chain length. Conditions are a fused silica capillary (60 cm \times 50 μ m i.d., 40 cm to detector) with a buffer of aqueous pH 7.0, 1.0 mmol L⁻¹ magnesium ion, 5.0 mmol L⁻¹ phosphate, 5.0 mmol L⁻¹ salicylate solution. Applied voltage is 30 kV, and indirect photometric detection is at 230 nm.

Other Anionics

Sodium salts of alkyl (C10–C14) sulfosuccinates are separated on a 250 \times 4.6 mm i.d. column of 10 μ m Nucleosil C8 with aqueous 0.01 mol L⁻¹ tetrabutylammonium hydrogensulfate–methanol (23 : 77) at pH 3 as mobile phase with refractive index detection.

Figure 7 C10 alkyl 3-ethoxylate.

methanol–20 mol L⁻¹ phthalic acid–water (3 : 5 : 12) and conductivity detection has been described.

Nonionic Surfactants

The two most common nonionic surfactants are ethoxylated alcohols and ethoxylated alkylphenols (Figure 7). Synthesis of alkyl ethoxylates is described above under AES. Alkylphenyl ethoxylates are synthesized similarly but with the added structural feature that the phenyl ring is attached at different carbon atoms along the alkyl chain. The alkyl chain is commonly nine carbon atoms.

Ethoxylated alcohols and alkylphenols can be separated by GC on a fused silica capillary column (30 m × 0.25 mm; 0.25 μm film) of SE-54 using helium as carrier gas and EI or CI (chemical ionization) (methane) MS detection. Temperature programming is from 70°C (1 min) to 300°C (10 min hold) at 3°C per minute. Ethoxylates up to 6 EO units are detected.

Separation of alkylphenyl ethoxylates and alkyl ethoxylates on an aluminium-clad fused silica column

(10 m × 0.53 mm i.d.) of OV-1 with helium as carrier gas, FID, and temperature programming to 325°C has been demonstrated. The hydrophobe distribution can be obtained via reaction to alkyl bromides as described above for AES.

Silylation of alcohol ethoxylates to their trimethylsilyl ether derivatives, when combined with temperature-programmed GC using a non-polar methylsilicone column, gives an extremely complex pattern of peaks (Figure 8).

HPLC analysis of alkyl ethoxylates is made complicated by the lack of a strong UV chromophore. Derivatization to introduce a chromophore is an option. Reaction to form phenyl isocyanate derivatives which can then be detected by UV after separation on a μ-Bondapak C18 column according to alkyl chain length or on a μ-Bondapak amine column according to degree of ethoxylation. The evaporative light-scattering detector reduces the need for derivatization for HPLC. Separation by ethoxamer is shown in Figure 9.

Alkylphenol ethoxylates can be readily detected by UV. Columns and separation conditions are similar

Figure 8 Separation of C12/C14/C16 3 EO alkyl ethoxylate as trimethylsilyl ethers. Column 10 m × 0.53 mm i.d. methylsilicone (1.0 μm film) programmed from 70°C to 240°C at 10°C minute, injector and detector 270°C, carrier helium at 15 mL min⁻¹, FID.

Figure 9 HPLC of C12/C14/C16 alkyl 3 EO ethoxylate. Column 250×4 mm i.d. Nucleosil 50 silica. Linear gradient: ethyl acetate–water (99 : 1, v/v) to acetone–water (90 : 10, v/v) over 60 min. Evaporative light-scattering detector.

to those for alcohol ethoxylates. Ethoxamer distribution can be determined on a LiChrosorb amine column (250×4.6 mm i.d.) with a hexane–isopropanol to aqueous isopropanol gradient system and UV detection at 277 nm.

Separation of ethoxylated fatty acids is obtained using a column (250×4.6 mm i.d.) of Nucleosil DIOL with hexane–isopropanol–water–acetic acid (105 : 95 : 10 : 1, v/v).

TLC can also be used for the determination of nonionic surfactants using a silanized silica gel GF254 layer with aqueous 80% methanol as developing solvent and a scanning densitometer at 525 nm for detection.

Alkylphenyl ethoxylates may be analysed using a Kieselgel F60 layer with chloroform–methanol as developing solvent. IR detection is feasible with such systems.

Supercritical fluid chromatography (SFC) has been extensively applied to analysis of alcohol ethoxylates. Examples are separation of ethoxylated alcohols on a 20 m×0.1 mm i.d. column of poly(dimethylsiloxane) with density programmed carbon dioxide at

100°C as mobile phase and FID. Response factor corrections are required for quantitative analysis. SFC can be used to determine alkyl chain distributions of ethoxylated alcohols after reaction with 50% HBr in glacial acetic acid to give their alkyl bromides.

An alternative to FID detection for SFC analysis of these molecules is evaporative light-scattering detection.

Cationic Surfactants

Cationic surfactants are generally based on a quaternary ammonium structure with a number of long (>C10) alkyl chains attached either directly to the nitrogen atom or through an ester linkage (Figure 10).

Figure 10 Dialkyldimethylammonium chloride. R_1 and R_2 are typically based on hardened tallow.
